APPENDIX 4.3 - HRA

HRA: Air Dispersion Modeling and Health Risk
Assessment Methodologies

APPENDIX 4.3

HRA: AIR DISPERSION MODELING AND HEALTH RISK ASSESSMENT METHODOLOGIES

This document describes the methods and results of a health risk assessment (HRA) that evaluates potential public health effects from toxic air contaminant (TAC) emissions generated by the operation associated with the Modernization Project. TACs are compounds designated by the California's Environmental Protection Agency's (Cal/EPA) Office of Health Hazard Assessment (OEHHA) as known or suspected to cause adverse health effects after short-term (acute) or long-term (chronic) exposure. In addition to naming certain chemicals as TACs, OEHHA also provides information that allows the prediction of health impacts associated with the public's potential exposure to TACs. This information is used in an HRA as described in this section to estimate the potential public health impacts resulting from TAC emissions from the Modernization Project.

In addition to evaluating TACs, this HRA also predicts the ambient air concentrations of particulate matter less than 2.5 microns in diameter (PM_{2.5}) and carbon monoxide (CO) to evaluate consistency with Bay Area Air Quality Management District (BAAQMD) California Environmental Quality Act (CEQA) thresholds for these chemicals. The methods used to estimate PM_{2.5} and CO emissions are described elsewhere, and will not be discussed further in this appendix. While the methods used to estimate TAC emissions are also discussed elsewhere, they are described here in more detail, as the specific TACs emitted from various processes strongly impact the results of the HRA.

The HRA process was designed to evaluate the health impacts of the Modernization Project, and to ensure that the Project scenario that resulted in the greatest health impacts was also evaluated. As will be discussed below, the emissions associated with marine traffic had the greatest impacts on the unmitigated health impacts. Accordingly, the Project scenario with the greatest marine traffic, the Lightest Crude Blend, was analyzed in addition to the Modernization Project Crude Blend scenario. Each of these scenarios was analyzed with and without project design features.¹

¹ The Project Design Features include upgrades to the SUEZMAX ships, and the installation of a single tank dome on tank 1491. The emissions reductions from the upgrades to the SUEZMAX ships was incorporated into the HRAs conducted for the cases with Project Design Features. However, the emissions reductions stemming from the

The HRA evaluated the incremental health effects associated with the:

- Project Crude Blend with Maximum Hydrogen Plant Production, 93% Utilization Scenario without Project Design Features;
- Project Crude Blend with Maximum Hydrogen Plant Production, 93% Utilization Scenario with Project Design Features
- Project Crude Blend with Maximum Hydrogen Plant Production, 100% Utilization Scenario without Project Design Features;
- Project Crude Blend with Maximum Hydrogen Plant Production, 100% Utilization Scenario with Project Design Features
- Lightest Crude Blend with Maximum Hydrogen Production, 93% Utilization Scenario without Project Design Features
- Lightest Crude Blend with Maximum Hydrogen Production, 93% Utilization Scenario with Project Design Features
- Lightest Crude Blend with Maximum Hydrogen Production, 100% Utilization Scenario without Project Design Features
- Lightest Crude Blend with Maximum Hydrogen Production, 100% Utilization Scenario with Project Design Features

The determination of health risks in this HRA required the calculation of average exposures to chemicals depending on the type of health impact analyzed for. Cancer risks require the evaluation of a 70-year average exposure for residents, and a 40-year average exposure for workers. Maximum annual emission rates during project operation were conservatively used to determine chronic non-cancer effects, given that the chronic exposure period for non-cancer effects is assumed to be approximately 12% of a 70-year lifetime, or 8 or more years (OEHHA, 2002). Maximum 1-hour emission rates were used to determine the acute hazard index (HI) because the acute exposure period is 1 hour for most TACs.

The extended period of analysis (up to 70 years for cancer risk) required predictions of the future operational characteristics of the proposed emission sources. Although Refinery Operations sources are assumed to operate in the future as they operate today, transportation sources, such as marine vessels and

installation of the single tank dome was conservatively not included in the HRAs with Project Design Features. This was because the tanks were modeled at the closest location to the residents. Were the emissions reductions modeled at this location, the reduction in health impacts would be overestimated.

trucks are assumed to have lower emissions in the future than they do today due to existing laws that require cleaner engines over time. Three important factors that would affect future emissions from transportation Project sources and that were integrated into the analysis are reductions in emissions due to:

- a) the incidental phase-in of cleaner vehicles or equipment due to normal fleet turnover;
- b) the future phase-in of cleaner fuels as required by existing regulations or agreements;
- c) the future phase-in of cleaner engines as required by existing regulations or agreements.

The HRA analyzed Project emissions and potential human exposure to carcinogens during the 70-year period from 2016 through 2085. In order to ensure that the incremental Modernization Project health impacts were not minimized as a result of cleaner fuels and engines that would result independent of the Modernization Project, the Baseline is based on the same 70-year period from 2016 through 2085.

Concentrations in the air are calculated from TAC emissions using air dispersion modeling. Air dispersion modeling is the mathematical estimation of pollutant impacts from emissions sources within a study area. Information on factors that impact the fate and transport of pollutants in the atmosphere including: meteorological conditions, site configuration, emission release characteristics, and surrounding terrain, are used in the dispersion model. Once concentrations are calculated using air dispersion modeling, the risks are calculated using information on how much air people breathe and the toxicity of the chemical considered. The resulting cancer risks and chronic and acute HI, as described above, are compared to the BAAQMD CEQA thresholds to assess significance.

The incremental carcinogenic and non-carcinogenic inhalation health risks from the Modernization Project were determined through dispersion modeling of the Modernization Project TAC emissions and applying OEHHA toxicity factors to the predicted TAC concentrations consistent with the BAAQMD (2010a) and OEHHA Hot Spots Guidance (OEHHA, 2003).

This HRA was prepared in accordance with the Recommended Methods for Screening and Modeling Local Risks and Hazards (BAAQMD, 2012). In general, the Protocol follows the methodology for preparing Tier 1 risk assessments described in The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (OEHHA, 2003). Prior to development of the HRA, the general approach and project-specific decisions were discussed with and reviewed by the BAAQMD prior to implementation.

1.1 OVERVIEW OF HEALTH RISK ASSESSMENT

Health risk assessments are used to estimate whether current or future chemical exposures will pose health risks to a broad population, such as a city or a community. Scientific methods used in health risk assessment cannot be used to link individual illnesses to past chemical exposures, nor can health risk assessments and epidemiologic studies prove that a specific toxic substance caused an individual's illness. In general, three types of health impacts are evaluated: cancer risk, chronic (long-term) health impacts, and acute (short-term) health impacts.

Consistent with OEHHA guidance, all chemicals that are emitted from the Modernization Project, and have toxicity values provided by OEHHA (OEHHA, 2014), were evaluated. The list of TACs evaluated in this assessment is contained in Table A4.3-HRA-1.

Individuals can be exposed to chemicals that are emitted into the air several different ways. They can breathe the air, and the chemicals in the air may remain in their lungs or may be absorbed into their bloodstream via the lungs. Chemicals in the air can be deposited on the ground and may come into contact through the skin (this is known as "dermal exposure") because an individual may touch the chemical that has deposited to the ground. The chemical may come into contact with food that an individual eats or may be ingested because it gets on the fingers of an individual. This is known as "oral exposure." Finally, infants can come into chemicals that may contaminate its mother's milk. OEHHA has designated which chemicals may result in risks from dermal, oral, and mothers' milk pathways. Only certain chemicals are recognized by OEHHA to have potential impacts by the oral, dermal or mother's milk routes. These chemicals are specified in the OEHHA Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis, Appendix E (OEHHA, 2012).

OEHHA Hot Spots Guidance (OEHHA, 2003, 2012) requires the evaluation of non-inhalation exposure pathways, referred to as a multi-pathway analysis, in risk assessments prepared to meet the 2010 BAAQMD CEQA Guidelines. Selection of the additional pathways for a multi-pathway analysis is specific to the chemical and land use designations in the area impacted by the facility.

Multi-pathway factors which represent the mathematical combination of the toxicity values and exposure parameters specific to this HRA can be generated to estimate health risks for the multi-pathway exposures by combining with the air modeling results.

The HRA process requires the completion of four general steps to estimate health impact results: (1) quantify project-generated TAC emissions; (2) identify ground-level receptor locations that may be affected by the emissions (including both a regular grid of receptors and any additional sensitive receptor locations such as schools, hospitals, convalescent homes, and/or daycare centers); (3) perform dispersion modeling analyses to estimate ambient TAC concentrations at each receptor location; and (4) use established methods to estimate potential health effects at each receptor location.

The first step in an HRA is to identify the TACs that are being emitted from a source, and quantifying the amount of chemicals emitted from each location. For sources of emissions that have not yet been constructed, like those associated with the Modernization Project, engineers use information about similar sources to estimate emissions, and locations of emissions. Once the identity and location of the sources of TAC emissions are known, the next step is to determine how it moves away from the sources into the ambient air.

For sources of emissions that have not yet been constructed, engineers use computer models to estimate the amount of pollutant at different distances from the source. Computer models use mathematical equations that represent the processes that occur when a facility releases a pollutant and also the movement of pollutants through the air. Factors such as distance from the source to exposed persons, wind speed and direction, and smokestack height affect these estimates.

The final step in an air pathway exposure assessment is to estimate the amounts each person inhales. To do this, scientists combine estimates of breathing rates and lifespan of an average person with estimates of the amount of pollutant in the air that person breathes. The exposure assessment also considers how much pollutant may reach the individual through contact with the skin or through ingestion.

Toxic air pollutants can cause health problems by interfering with normal body functions. Most commonly they change chemical reactions within individual cells, the building blocks of living things. These changes can kill cells, impair cell function, or re-direct cell activity. The results can be damaged organs, birth defects when the cells of an unborn child are damaged, or cancer that develops when cells begin to grow at an uncontrolled rate.

The dose-response relationship for a specific pollutant describes the association between exposure and the observed response (health effect). In other words, it estimates how different levels of exposure to a pollutant change the likelihood

and severity of health effects. Scientists use results of animal and human studies to establish dose-response relationships.

In the absence of clear evidence to the contrary, United States Environmental Protection Agency (EPA) and OEHHA assume that there are no exposures that have "zero risk"—even a very low exposure to a cancer-causing pollutant can increase the risk of cancer (albeit a small amount). EPA and OEHHA also assume that the relationship between dose and response is a straight line—for each unit of increase in exposure (dose), there is an increase in cancer response.

For non-cancer causing chemicals, a dose may exist below the minimum health effect level for which no adverse effects occur. EPA and OEHHA typically assume that at low doses the body's natural protective mechanisms repair any damage caused by the pollutant, so there is no ill effect at low doses. However, for some substances, non-cancer effects may occur at low doses. The dose-response relationship (the response occurring with increasing dose) varies with pollutant, individual sensitivity, and type of health effect.

Risk assessment results are presented as calculated cancer risks and non-cancer hazards during the risk characterization step. Cancer risk estimates represent the probability of cancer (presented as a probability per million people) related to potential exposures to pollutants evaluated in the HRA. Non-cancer hazards are represented as the ratio between the estimated dose (i.e., intake of chemical) and chemical-specific reference exposure level developed and approved by Cal/EPA for a specific health endpoint (e.g., eye or lung irritation). The cancer risk or non-cancer HI estimate is then compared to a threshold level that is intended to be protective of public health. This comparison aids the Lead Agency in prescribing appropriate actions to mitigate risks, if needed. If cancer risk estimates exceed the significance level, then all feasible mitigation must be applied to the project.

1.1.1 Quantification of Project TAC Emissions

The major sources of emissions of TACs from Refinery Operations are stationary sources, such as furnaces and process units used to heat, chemically modify, and separate crude oil and purchased gas oils feedstock to the Facility into marketable products such as gasoline, diesel, jet fuel, and lubricants. Refinery Operations also generate fugitive emissions from tanks and process components, such as pumps and flanges on pipelines. Emissions are also generated from combustion sources involved in the transportation of feedstocks brought into and marketable products transported from the Facility. Transportation-related combustion air emissions sources include vessels associated with marine shipping, locomotives associated with rail transport and trucks associated with bringing materials into and out of the Facility.

The quantification of TAC emissions generated by the Project is described in several other appendices to the *Section 4.3, Air Quality* of this Environmental Impact Report (EIR), and tables quantifying TAC emissions are contained in this appendix. Estimation of Refinery Operations emissions in *Appendix 4.3-OP*. Emissions associated with shipping feedstock to and products from the Facility are described in *Appendix 4.3-SHP*, and emissions associated with material transport to and from the Facility by rail and truck are discussed in *Appendix 4.3-TRANS*. The methodology used to estimate TAC emissions for each of these sources is also briefly described here.

Due to the fact that the rail activities were small relative to the large railyard operation adjacent to the Facility, and that the emissions associated with rail activities were small relative to the emissions associated with shipping, risks from incremental rail activities were not quantitatively evaluated in this HRA.

1.1.1.1 Estimation of TAC Emissions

Potential TAC emissions associated with Modernization Project operations were evaluated by comparing TAC emissions for a range of future scenarios with Baseline emission levels. Modernization Project TAC emissions were calculated by using an analysis tool called a Unit Rate Model (URM)² developed by independent petroleum refinery experts retained by the City. The URM estimates how Facility operations change when the Facility refines heavier or lighter crude oil blends, crude and purchased gas oil with higher and lower sulfur content, and operates at higher or lower utilization levels than during 2008-2010. In consultations with the BAAQMD, the URM results were used to scale Baseline Refinery Operations, shipping and truck and rail emission levels to generate TAC emissions for each future scenario evaluated in this EIR. If the throughput for a certain Facility processing unit increased from Baseline utilization levels by 20% in a scenario, for example, Baseline TAC emissions for that unit were increased by 20%, if the unit were not modified as a result of the Modernization Project. If the unit were modified as a result of the Modernization Project, emissions for the modified source were estimated consistent with the methods used in the BAAQMD Engineering Evaluation for the Modernization Project.

² The URM also responds to the writ, which directed the City to evaluate whether the Modernization Project would enable the Facility to refine different types and volumes of crude oil, and to evaluate potential emission consequences that might be associated with any such use. As discussed below, and in more detail in *Appendix 4.3-URM*, the URM was used to evaluate Facility operations, and operational limitations related to physical and permit constraints, for a range of very heavy, very light, high sulfur and utilization rates ranging from 93% (higher than the 2008-2010 utilization rate of approximately 89%) up to 100% (the theoretical maximum level that, in practice, cannot feasibly be sustained).

This proportional scaling is generally true for most sources, but it is not true for every source. For example, there are small emissions from joints (called flanges) and pumps along piping at the Facility. These very small emissions sources are accounted for in the BAAQMD Emissions Inventory (EI), as aggregated emissions sources associated with groups of piping racks. These small emissions would occur if the piping has material in it, and do not increase if more material is transported through piping. As a result, the emissions associated with piping joints and pumps do not increase with increased refinery throughput. Similarly, emissions from tanks used to hold crude oil and refined products in the Facility do not increase proportionally with throughput. Small emissions from tanks come from the seals around the tanks, and, similar to the case with piping, emissions result from the storage (and not throughput) of crude oil and refined products. Some of the emissions from the tanks are associated with the fact that stored material is pumped in and out of a tank. Those emissions increase with increasing throughput. Finally, some process units are not expected to change process rates as a result of the Modernization Project. An example of this is the electricity generating units. The Modernization Project includes additional electricity generation in the new hydrogen plant. Accordingly, the existing electrical generating units are not expected to increase electricity production as a result of the Modernization Project. This is fully described in *Appendix 4.3-OP*.

The emissions from Refinery Operations, shipping and trucking are described below. The total TAC incremental emissions for all Project scenarios that were analyzed in this HRA are shown in Table A4.3-HRA-2.

1.1.1.2 Refinery Operations

The methods used to estimate emissions are fully described in *Appendix 4.3-OP*, and summarized here.

The methods of emissions analysis for operations were developed based on BAAQMD, California Air Resources Board (CARB), and EPA guidance, BAAQMD engineering evaluation of project components, and extensive consultation with BAAQMD staff. The methods presented in this appendix reflect the outcome of these meetings with the BAAQMD, and reflect the results of the consensus formed between the City of Richmond's consultants, and the BAAQMD.

After reviewing available regulatory reporting and tracking studies, for purposes of this EIR and in consultation with the BAAQMD, the BAAQMD EI was determined to provide the most comprehensive ongoing framework for understanding Refinery Operations emissions, and for evaluating Modernization Project emissions. In determining the TAC emissions, all chemicals for which data were available from the BAAQMD EI and which were included in BAAQMD's Regulation 2, Rule 5 methodology for evaluating TACs from new stationary sources

Note: lbs/year = pounds per year, SRU = sulfur recovery unit; ICR = Information Collection Request

^a These chemicals [shaded] were evaluated in the HRA (either cancer risk, chronic non-cancer hazard, or acute non-cancer hazard). All but hydrogen sulfide are included in BAAQMD Regulation 2, Rule 5, but hydrogen sulfide has a California Ambient Air Quality Standard.

^b These chemicals are associated with refinery fuel gas combustion.

^c These chemicals are only listed as combustion TACs in the Engineering Evaluation (i.e., for the replacement hydrogen plant and the SRU); hence, the large increase in emissions. They are not listed as combustion TACs in the Baseline EI for TACs.

^d These chemicals are associated with fugitive emissions from equipment leaks in the Engineering Evaluation.

^e These chemicals are associated with the new hydrogen plant cooling water tower in the Engineering Evaluation.

^f These chemicals are only associated with emergency diesel engines, maintenance operations, and equipment fugitives, none of which scale with throughput or are otherwise affected by the project. A small amount of 1,2-dibromoethane was listed in the EI as part of “gasoline – leaded emissions from storage tanks”; this speciation profile was replaced with the EPA’s ICR speciation profile for reformulated gasoline, at the direction of the BAAQMD.

^g These chemicals are unspciated emissions from storage tanks, as listed in the BAAQMD EI. At the BAAQMD’s direction, any such material with Project (93% Utilization Scenario) incremental emissions greater than 1,000 lbs/year was speciated with the EPA’s ICR profile for reformulated gasoline. This included unleaded gasoline, lube oil, “other hydrocarbons,” alkylate, crude oil, leaded gasoline, naphtha, and distillate oil.

^h These chemicals decrease with the Modernization Project because they were largely associated with the existing hydrogen plant in the EI, much more than any other sources, and were either not included in the Engineering Evaluation for the replacement hydrogen plant or had significantly lower emission factors.

ⁱ Carbon disulfide and sulfuric acid mist decrease with the Modernization Project due to improvements in the SRU.

Source: *Appendices 4.3-OP, 4.3-SHP, and 4.3-TRANS.*

(BAAQMD, 2010c) or had quantitative toxicity information published by OEHHA (2014), were included in the HRA.

The major sources of emissions of TACs from the Refinery Operations are stationary facilities, such as furnaces and process units used to heat, treat, and separate crude and gas oils into marketable products such as gasoline, diesel, jet fuel, and lubricants. In addition, the Refinery Operations generate emissions from tanks and process components, and emissions from transportation, including shipping, and to a lesser extent, rail and trucking. The locations of major operations, and therefore major sources of emissions, at the Facility are highlighted in Figure A4.3-HRA-1.

Emissions from the Refinery Operations vary with overall utilization: greater utilization results in greater emissions from process units at the Facility, as more fuel is required to process more feedstock. Emissions from the Refinery Operations also vary based on the utilization of specific process units, which vary, in some cases, based on the type of feedstock. Higher sulfur feedstocks require greater use of the hydrogen plant and the sulfur recovery unit (SRU). These higher unit utilization levels translate into greater emissions from these units. As described earlier, some emissions sources, such as small leaks from joints in piping, do not increase with increased throughput.

The Baseline TAC emissions were based on the BAAQMD EI. The BAAQMD EI contains information on chemical emissions for each Refinery Operations source. In some cases, the information is presented for individual chemicals, such as benzene and toluene. In other cases, the emissions information is presented for groups of chemicals, such as “crude oil” or “av gas.” The ultimate use of the TACs EI is to evaluate the impact of chemical emissions on public health. While there is information on the public health impacts of individual chemicals, there is little information on the public health impacts of blends of chemicals. Accordingly, a methodology was needed to split the groups of chemicals found in the BAAQMD EI into individual chemicals.

The BAAQMD specified that groups of chemicals be characterized as individual chemicals using the EPA Refinery Information Collection Request (ICR) document (RTI, 2011). Most groups of chemicals in the BAAQMD EI were from vapor emissions from liquids being held in tanks at the Facility. Therefore, speciation profiles of vapor emissions were required. Although the EPA ICR document provided liquid speciation profiles for a number of materials, the only vapor speciation profile available was for reformulated gasoline. Reformulated gasoline contains a higher proportion of TACs in the liquid phase than other materials listed in the EPA ICR document. As a result, the vapor emissions of reformulated

gas would also contain a higher proportion of TACs than other materials listed in the EPA ICR document. This is more fully described in *Appendix 4.3-OP*.

To be conservative, as agreed with the BAAQMD, the speciation profile for reformulated gas vapors was used to identify the chemical species in all groups of chemicals listed in the EI with emissions greater than 1,000 pounds per year (lbs/year) increase between Baseline and Modernization Project (93% Utilization with maximum hydrogen plant usage) emissions. This accounted for more than 90% of groups of chemical emissions and included unleaded gasoline, lube oil, “other hydrocarbon mixtures,” alkylate, crude oil, leaded gasoline (leaded av gas), naphtha, and distillate oil. The use of the reformulated gasoline vapor speciation profile to these 90% of the groups of chemicals results in a conservative estimate of TAC emissions. No speciation profile was used for the balance of the groups of chemical emissions.

The incremental TAC emissions for all of the Modernization Project cases of Refinery Operations for which HRAs were conducted are shown in Table A4.3-HRA-3. Table A4.3-HRA-3 contains all of the TACs from the BAAQMD TAC EI split into individual chemical constituents as described above. The rows that contains chemicals for which either the BAAQMD or OEHHA has assigned quantitative health effects information, and are therefore included in the health risk assessment, are highlighted. Some of the chemicals, such as benzo(a)anthracene, appear in the project inventories, but not in the Baseline inventory. This is because the BAAQMD Engineering evaluation included benzo(a)anthracene as a TAC resulting from combustion, whereas the BAAQMD TAC EI did not. Other chemicals, such as 1,3-butadiene, do not appear to change with project scenario. This is because the bulk of the 1,3-butadiene is associated with small leaks from the joints and pumps in the new piping for the hydrogen plant. Some chemicals, such as benzo[a]pyrene are reduced, because they are listed in the BAAQMD EI as being emitted from the old hydrogen plant, but are not considered to be emitted by the new hydrogen plant. As noted earlier, the emissions that result from these small leaks are independent of Facility throughput. As described in the footnotes to the table, there are other chemicals associated with fugitive emissions or other sources, such as emergency generator usage, whose emissions do not scale with the Modernization Project.

1.1.1.3 Shipping

The Facility imports crude oil, gas oil and some blendstocks and exports a portion of its refined products and some gas oil, blendstocks, and base oils via ships and barges. This waterborne transport includes self-propelled ocean-going vessels (OGVs – i.e., tanker ships) and vessels that are not self-propelled (i.e., barges) that dock at the Long Wharf and either unload and/or load liquid materials over the dock. Both the OGVs and barges require assistance from

^a These chemicals [shaded] were evaluated in the HRA (either cancer risk, chronic non-cancer hazard, or acute non-cancer hazard). All but hydrogen sulfide are included in BAAQMD Regulation 2, Rule 5, but hydrogen sulfide has a California Ambient Air Quality Standard.

^b These chemicals are associated with refinery fuel gas combustion.

^c These chemicals are only listed as combustion TACs in the Engineering Evaluation (i.e., for the replacement hydrogen plant and the SRU), hence the large increase in emissions. They are not listed as combustion TACs in the Baseline EI for TACs.

^d These chemicals are associated with fugitive emissions from equipment leaks in the Engineering Evaluation.

^e These chemicals are associated with the new hydrogen plant cooling water tower in the Engineering Evaluation.

^f These chemicals are only associated with emergency diesel engines, maintenance operations, and equipment fugitives, none of which scale with throughput or are otherwise affected by the project. A small amount of 1,2-dibromoethane was listed in the EI as part of “gasoline – leaded emissions from storage tanks; this speciation profile was replaced with the EPA’s ICR speciation profile for reformulated gasoline, at the direction of the BAAQMD.

⁹These chemicals are unspciated emissions from storage tanks, as listed in the BAAQMD EI. At the BAAQMD's direction, any such material with Project (93% Utilization Scenario) incremental emissions greater than 1,000 lbs/year was speciated with the EPA's ICR profile for reformulated gasoline. This included unleaded gasoline, lube oil, "other hydrocarbons", alkylate, crude oil, leaded gasoline, naphtha, and distillate oil.

¹⁰These chemicals decrease with the Modernization Project because they were largely associated with the existing hydrogen plant in the EI, much more than any other sources, and were either not included in the Engineering Evaluation for the replacement hydrogen plant or had significantly lower emission factors.

¹¹Carbon disulfide and sulfuric acid mist decrease with the Modernization Project due to improvements in the SRU.

Source: *Appendix 4.3-OP*.

smaller ships called tugs (also called harbor craft). The OGVs, barges, and tugs utilize engines fueled by fossil fuels to perform their operations; thus emit TACs as part of their routine operation at the Long Wharf. The amount of material transported to and from the Facility via marine shipping determines how many vessels call at the Long Wharf, and in turn, the emissions from shipping activities. OGVs, barges and tugboats emit diesel particulate matter (DPM). OGVs also emit some TACs that are found in the volatile organic compounds emitted from boiler operation.

Total crude and gas oil volumes for the Modernization Project were estimated using the URM, as described in *Appendix 4.3-URM*. The feedstock volumes are dependent on the crude blend and refinery utilization rate, which was also determined by the URM.

The HRA analyzed Project emissions and potential human exposure to carcinogens during the 70-year period from 2016 through 2085. In order to ensure that the incremental Modernization Project health impacts were not minimized as a result of cleaner fuels and engines that would result independent of the Modernization Project, the Baseline is based on the same 70-year period from 2016 through 2085.

TAC emissions were estimated for any shipping activity that occurs within the HRA boundary (i.e., within 5 nautical miles of the Long Wharf) and comprehensively includes emissions from transit, maneuvering, and at-berth activities. The TAC emissions inventory includes chemicals emitted from sources that are included for consideration in HRAs consistent with BAAQMD Regulation 2, Rule 5, or have quantitative toxicity information provided by OEHHA (OEHHA 2014). The Baseline and Project TAC inventory for evaluation in the HRA from shipping are contained in Table A4.3-HRA-4.

1.1.1.4 Trucking

The methods used to estimate trucking emissions are more fully described in *Appendix 4.3-TRANS*, with a summary provided here. The Modernization Project includes on-road mobile emission-generating sources such as trucks delivering propane and other chemicals and removing sulfur, sodium bisulfite, products, and solid and hazardous wastes from the Facility. TAC emissions from on-road worker vehicles associated with operations were not included as the increase in workers (i.e., 29 additional workers) and associated increases in worker vehicle trips and emissions due to the Modernization Project are assumed to be negligible.

Trucking emissions for the Modernization Project are impacted both by the increase in emissions that would result from the change from baseline utilization

to a reasonably foreseeable utilization, and by the processing of a wider variety of fuels, as sulfur produced by the Facility is removed by trucking. Therefore, the processing of higher-sulfur fuels would result in more trucks transporting sulfur away from the Facility.

On-road mobile emissions were estimated using methods consistent with CalEEMod™, using emission factors from CARB's EMFAC2011 database. EMFAC is California's model for estimating emissions from on-road vehicles operating in California, and EMFAC2011 is the latest version of that model. The data required to estimate on-road mobile emissions include: trip counts and trip lengths, fuel type, fleet mix, model years, and travel speeds. The emissions calculated for trucks include running, idling, brake wear, and tire wear emissions. The truck startup emissions were not quantified because EMFAC2011 does not provide startup emission factors for diesel trucks.

For annual TAC emissions estimation, the baseline period emissions were estimated using 2010 emission factors with baseline activity data. The baseline was adjusted by projecting actual baseline emissions to the year 2016. Modernization Project emissions were estimated for year 2016. Modernization Project annual emissions were conservatively estimated for the year 2016 because each subsequent year would have lower emissions from on-road mobile sources than 2016 due to cleaner fleets in subsequent years. This method provides a conservative estimate of future emissions from trucking, and the health impacts associated with trucking. The TAC associated with trucking is DPM.

DPM emissions were calculated for on-road trucks from on-site delivery locations to the highway ramps. The number of Modernization Project-related trucks on highways is very small relative to highway background traffic; because of this, their emissions would not have a significant health impact on the sensitive population located along the highways. Accordingly, receptors that are exposed only due to their proximity to a highway that may be used by trucks going to and from the Richmond facility were not included in the HRA. The TAC inventory does include Modernization Project-related truck emissions associated with travel along Richmond Parkway, Castro Street, and the highway ramps taken by the vehicles to get on or off the highways.

On-road mobile sources do not have emission factors specifically for DPM in the CARB's emission factor databases (EMFAC). DPM is a subset of particulate matter less than 10 microns in diameter (PM_{10}). PM_{10} engine exhaust emissions from on-site on-road vehicles that were calculated for the CAP inventory for on-site sources were used as conservative, surrogate estimates for DPM. TAC estimates for trucking are shown in Table A4.3-HRA-5.

1.2 USE OF A DATABASE TO COMBINE EMISSIONS, EXPOSURE, AND TOXICITY INFORMATION CALCULATE RISKS

Risk assessments conducted to the standards required by the BAAQMD and OEHHA may involve sizeable data sets in order to thoroughly analyze the impacts from a large project, like the Modernization Project. In the case of the Modernization Project, over 50 TACs are emitted from over 150 different sources associated with the Project, including Refinery Operations and shipping. In order to carefully analyze impacts on the community, the evaluation was conducted at over 8000 locations in the community. In order to evaluate large data sets some type of database is typically programmed to allow for efficient calculations.

The Hotspots Analysis and Reporting Program (HARP) is a tool that assists with the programmatic requirements of the Air Toxics "Hot Spots" Program. The Air Toxics "Hot Spots" Program has the same risk assessment requirements as does the BAAQMD for CEQA. HARP is a single integrated software package that can be used by the air pollution control and air quality management districts (districts), facility operators, and other parties to promote statewide consistency, efficiency, and cost-effective development of health risk assessments. While HARP is a useful tool, it does not permit the analysis of data sets as large as that required for the Modernization Project. In addition, HARP does not allow the evaluation of time-changing activities, such as construction, which operate only 10 hours in a 24-hour day. Finally, HARP does not incorporate the childhood cancer sensitivity factors required for use by the BAAQMD.

In order to analyze the large dataset required for the Modernization Project, ENVIRON, the City's Consultants, programmed a Microsoft Access 2010 database to mimic the functions of HARP for the inhalation pathway. The non-inhalation pathways were evaluated in a separate Microsoft Access database. The resulting programmed Microsoft Access database used to mimic the inhalation pathway of HARP is called the Super Automated Risk Assessment Database (SARAD). The City's Consultants, have used forms of this database for years to analyze risks for permitting projects and CEQA projects. The Microsoft Access database used for the multi-pathway analysis then scaled the inhalation risks and chronic hazards by the multi-pathway scaling factors derived from HARP version 1.4f to estimate chronic hazards in the SARADs for each multi-pathway chemical.

SARAD calculates the health impacts that someone could experience as a result of the project at each of 8000 locations in the community for a variety of potentially exposed populations: a child, a worker, or an adult resident. SARAD does this by using information on emissions from each source that changes as a result of the Modernization Project, information on how the chemical moves in the air from the source to the receptor, information on the breathing rates of each exposed population, and information on the toxicity of the chemical. At each receptor, SARAD allows the addition of the concentrations of each chemical

that results from each source. It then calculates the health impacts that result from each chemical and sums the health impacts across chemicals. The result is an estimate of health impacts at every location for every type of exposed population.

Attachment 3 to this appendix describes the evaluation conducted to show equivalence between SARAD and HARP to confirm that the results from SARAD are the same as would result if HARP could be used for this evaluation.

Attachment 4 to this appendix contains the emission rate by source group and dispersion factor by source group at the maximum exposed individual (MEI) locations.

1.3 EVALUATION OF NON-INHALATION EXPOSURE PATHWAYS

There are two types of exposures in addition to airborne exposure that need to be considered in this HRA: evaluation of lead for noncancer impacts, and the evaluation of multipath exposure for airborne emissions.

1.3.1 Noncancer Impacts of Lead

Lead is unique among TACs in several ways. First, children are particularly susceptible to levels of lead in their blood due to exposure to lead. Second, the chronic noncancer effects are related to blood lead levels as opposed to ambient air concentrations. These blood lead levels reflect current and past exposure from a number of sources; air emissions may only be a small part of the total exposure. Third, OEHHA did not identify a threshold level for acute or chronic non-cancer health effects due to exposure to lead air concentrations. Recognizing the unique aspects of lead risks, OEHHA developed special risk management guidelines.

The potential cancer health effects of lead were evaluated in the health risk assessment using the cancer potency factor recommended by OEHHA/CARB. OEHHA/CARB does not have a chronic reference exposure level for evaluation of the non-cancer effects of lead. Instead the potential non-cancer health effects of lead were evaluated using the screening methodology recommended by the CARB in their 2001 document “Risk Management Guidelines for New, Modified, and Existing Sources of Lead” (“2001 CARB Guidelines”).

The 2001 CARB Guidelines provides a simplified, screening-level approach to evaluate non-cancer risks using the neurodevelopmental risk as a surrogate. The simplified approach uses a 30-day maximum off-site concentration to determine a maximum exposure area (MEA), which is the area surrounding the maximum

off-site concentration (equivalent to the size of a square area with side lengths of 1 kilometer). Using this simplified approach, the CARB derived recommended risk management levels for assessing non-cancer risks. The risk management levels take into account both direct exposures from the facility (project) and exposure due to background concentrations in the environment.

Although the approach is conservative, meaning that a project that passes the screening level criteria is unlikely to pose a health risk; it is not conservative enough to be used for a source in a high exposure area. To determine if the source is in a high exposure area, an evaluation of the census tracts within the MEA is conducted. If the MEA does not overlap with any census tract where the median year of construction for housing is 1960 or earlier and more than 30 percent of the population has an income less than 1.25 times the poverty level; then it is not considered a high exposure area. The median year of construction for housing in Richmond is 1962. The median year within the MEA is unknown.

The CARB recommended risk management levels are as follows:

Lead Permitting Levels		Hot Spots Program Levels	
T-BACT trigger level	Emissions $\geq$ 1 pound per month	Notification level ¹	Maximum off-site air concentration $\geq$ 0.30 $\mu\text{g}/\text{m}^3$
Approvable level ¹	Maximum off-site air concentration $\leq$ 0.30 $\mu\text{g}/\text{m}^3$	Significant risk level ¹	Maximum off-site air concentration $\geq$ 0.30 $\mu\text{g}/\text{m}^3$
Permit denial level ¹	Maximum off-site air concentration $\geq$ 0.55 $\mu\text{g}/\text{m}^3$	Unreasonable risk level ¹	Maximum off-site air concentration $\geq$ 0.55 $\mu\text{g}/\text{m}^3$ ^a

Note: $\mu\text{g}/\text{m}^3$ = micrograms per cubic meter

^a Not applicable to high exposure areas.

The maximum incremental off-site lead ambient air concentration is 0.0002 micrograms per cubic meter ($\mu\text{g}/\text{m}^3$), far below the 0.30 $\mu\text{g}/\text{m}^3$ recommended risk management level for notification and significant risk. This means that the project is unlikely to pose a health risk to off-site population due to the non-cancer health effects of lead.

It should be noted that the screening-level approach used to develop the risk management levels was based on a blood lead level of concern of 10 micrograms per deciliter ($\mu\text{g}/\text{dl}$). More recently, the Centers for Disease Control and Prevention has recommended a reference level of 5 $\mu\text{g}/\text{dl}$ to identify children

with a blood lead level that is much higher than most children's levels. However, the maximum concentration is orders of magnitude below the approvable level, therefore, the project is unlikely to pose a health risk to off-site populations due to the non-cancer health effects of lead.

1.3.2 Assessment of Multi-Pathway Non-Inhalation Pathways

OEHHA Hot Spots Guidance (OEHHA, 2003) requires the evaluation of non-inhalation exposure pathways, referred to as a multi-pathway analysis, in risk assessments prepared to meet the 2010 BAAQMD CEQA Guidelines. Selection of the additional pathways for a multi-pathway analysis is specific to the chemical and land use designations in the area impacted by the facility. As shown on Table A4.3-HRA-6, the chemicals that are emitted from the refinery and shipping activities at the Facility and must be evaluated in a multi-pathway analysis are: arsenic, beryllium, cadmium, chromium (VI), lead, mercury, nickel, and polycyclic aromatic hydrocarbons (PAHs) including benzo(a)pyrene, b(a)anthracene, benzo(b)fluoranthene, benzo(k)fluoranthene, chrysene, dibenz(a,h)anthracene, and indeno(1,2,3-cd)pyrene.

HARP version 1.4f developed by CARB was used to generate multi-pathway scaling factors. These factors were then used to scale the inhalation risks and hazard quotients (HQs) calculated in SARADs for the multi-path chemicals to estimate cancer risks and non-cancer chronic hazards from the multi-pathway exposures. Consistent with the recommendations in the OEHHA Hot Spots Guidance for conducting a multi-pathway analysis, a 70-year resident was conservatively assumed to be exposed to Facility emissions via inhalation, dermal contact with soil, incidental ingestion of soil, ingestion of homegrown produce, and ingestion of mother's milk. Because the operational emissions are primarily coming out of stationery sources that have various pollution control devices the default deposition rate of 0.02 meters per second for controlled sources was used to generate the multi-pathway scaling factors in HARP. The HARP health value database, which reflects the updates in the CARB consolidated health value table (OEHHA, 2014), was used. Unit air concentrations for all multi-pathway chemicals identified above were assumed in this analysis in HARP.

Since the Facility is located in an urban area with no agricultural areas (e.g., cattle grazing areas) in the vicinity, this multipath assessment does not include an evaluation of potential exposures via ingestion of meat, milk, or eggs. However, potential exposures to chemicals in homegrown produce were evaluated for a resident in this HRA because it is possible that residents in the area may have small vegetables gardens exclusively for personal use.

Ingestion of fish is not considered a complete exposure pathway for residents. A portion of the San Francisco Bay lies in the immediate area of the Facility.

Evaluation of potential impacts on fish that inhabit the San Francisco Bay is not recommended. Specifically, OEHHA states that “although regional air contaminants depositing into the ocean, bays and estuaries are a significant problem, the risks predicted from a single source are relatively insignificant due to tidal flows and dilution” (OEHHA, 2012).

HARP allows a user to select from a series of exposure analysis methods. Each method in HARP utilizes exposure assumptions differently, depending on the requirements of a specific regulation (i.e., compliance with CARB’s Air Toxics Hot Spots Program) or project need (i.e., provide point estimates for risk management decisions). That is, HARP will select the dominant pathway(s) and assign exposure assumptions depending on the exposure analysis method identified by the user. For this HRA, each exposure analysis method selected is described below.

1.3.2.1 Resident

Consistent with HARP and OEHHA Hot Spots Guidance (OEHHA, 2003), cancer risks for residential populations were calculated using the Derived (Adjusted) Analysis Method. This method applies high-end exposure assumptions to the two dominant exposure pathways for each chemical. The remaining pathways are evaluated using average exposure assumptions. If inhalation is one of the two dominant exposure pathways, then it is evaluated using the 80th percentile breathing rate (302 L/kg-day).

As required in OEHHA Hot Spots Guidance (OEHHA, 2003) and BAAQMD Health Risk Screening Analysis Guidelines (BAAQMD, 2010a) for preparing a Tier 1 risk assessment under AB2588, it was assumed that a resident may be exposed to Facility emissions for their entire lifetime (70 years). Cancer risks estimated assuming a residential exposure duration of 70 years are used by State and local agencies for risk management and public notification purposes. Specifically, OEHHA Hot Spots Guidance states that “Lifetime or 70-year exposure is the historical benchmark for comparing facility impacts on receptors for evaluating the effectiveness of air pollution control measures (OEHHA, 2003).” Use of the 70-year exposure duration in risk assessments is intended to produce a hypothetical estimate of risk that does not underestimate risks and that can be viewed as an upper-bound estimate.

As discussed previously, it was assumed that individuals residing in the vicinity of the Facility may ingest produce obtained from vegetable gardens grown at their homes. Ingestion of homegrown produce is estimated by applying a default parameter of 5.2%. This value reflects the percentage of total produce ingested by individuals in an urban setting that is homegrown, and is comprised of root and leafy vegetables.

The Derived (OEHHA) Analysis method was used to calculate chronic non-cancer HIs for the resident. This method, as previously noted, utilizes high-end exposure assumptions to the two dominant pathways for each chemical. The remaining pathways are evaluated using average exposure assumptions.

To generate the cancer risk multi-pathway scaling factors, the derived (adjusted) method and default exposure settings for a 70-year resident as recommended in the OEHHA Hot Spots Guidance and BAAQMD Health Risk Screening Analysis Guidelines (BAAQMD, 2010a) were used in HARP. This receptor population represents the most conservative exposures among all receptor populations evaluated for the Project. ENVIRON conducted two sets of analysis in HARP to calculate cancer risks for each of the multi-pathway chemicals for: (1) inhalation pathway only; and (2) all non-inhalation pathways identified above. The methodologies and equations used in HARP to estimate chemical concentrations in each medium, doses and cancer risks for each exposure pathway are consistent with the recommendations in the Hot Spots Guidance. The cancer risk multi-pathway scaling factors for each of the multi-pathway chemicals were then derived based on cancer risk results from the two sets of analysis using the following equation:

$$\text{Cancer Risk Multipathway Factors} = \frac{\text{All Pathway Risk} - \text{Inhalation Cancer Risk}}{\text{Inhalation Cancer Risk}}$$

As shown in the equation above, because the inhalation pathway risk is subtracted from the all pathway risk, the cancer risk multi-pathway scaling factor derived from this method does not reflect the scaling between the inhalation pathway risk and the all pathway risk. Instead the scaling factor reflects the scaling between the inhalation pathway risk and the non-inhalation multi-pathway risk.

Similarly, to generate the non-cancer chronic HQ multi-pathway scaling factors, the derived (OEHHA) method and default exposure settings for a resident as recommended in the OEHHA Hot Spots Guidance were used in HARP. ENVIRON conducted two sets of analysis in HARP to calculate the non-cancer chronic HQs for each of the multi-pathway chemicals for: (1) inhalation pathway only; and (2) all non-inhalation pathways identified above. The equations used in HARP to estimate chemical concentrations in each medium, doses and non-cancer hazards for each exposure pathway are consistent with the methodology recommended in the Hot Spots Guidance. The chronic HQ multi-pathway scaling factors for each of the multi-pathway chemicals were then derived using the maximum all-pathway chronic HQ among all target organs over the maximum inhalation chronic HQ among all target organs using the following equation:

Chronic HQ Multipathway Factors

$$= \frac{\text{Max All Pathway Chronic HQ} - \text{Inhalation Max Chronic HQ}}{\text{Inhalation Chronic HQ}}$$

As shown in the equation above, because the maximum inhalation pathway chronic HQ is subtracted from the all pathway maximum chronic HQ, the chronic HQ multi-pathway scaling factor derived from this method does not reflect the scaling between the maximum inhalation pathway chronic HQ and the maximum all pathway chronic HQ. Instead the scaling factor reflects the scaling between the maximum inhalation pathway chronic HQ and the maximum non-inhalation multi-pathway chronic HQ.

The derived “cancer risk multi-pathway scaling factors” and the “chronic HQ multi-pathway scaling factors” were then imported to a separate multi-pathway database” to estimate cancer risks and chronic HQs for the multi-pathway exposures by applying these scaling factors to the calculated inhalation risks and chronic HQs in the SARADs for each multi-pathway chemical accordingly using the following equation:

Multipathway Cancer Risk

$$= \text{Inhalation Cancer Risk} \times \text{Cancer Risk Multipathway Scaling Factor}$$

Multipathway Chronic HQ

$$= \text{Inhalation Chronic HQ} \times \text{Chronic HQ Multipathway Scaling Factor}$$

As shown on Tables A4.3-HRA 7 through 10, the non-inhalation pathway estimated incremental cancer risks for a 70-year lifetime resident at the maximally exposed individual resident location are negative for the Refinery Operations sources and 0.0004 in 1 million for the shipping sources, respectively. The multi-pathway risks from refinery sources are reduced because of the reduction of benzo[a]pyrene as a result of the Modernization Project. The estimated incremental chronic HIs at the MEI location³ are 0.1 for the refinery sources and 0.0005 for the shipping sources, respectively. Therefore, the cancer risks and non-cancer hazards associated with the multi-pathway exposures are small compared to the thresholds for cancer risks and non-cancer chronic hazards.

³ This is a worker location at the quarry area.

1.4 ESTIMATING AIR CONCENTRATIONS USING AIR DISPERSION MODELING

In order to estimate risks, ambient air concentrations resulting from the Modernization Project must be evaluated. This is done by simulating the dispersion of emissions into the air using a mathematical simulation, called air dispersion modeling. Details on the methodologies used to estimate TAC, PM_{2.5} and CO concentrations in the ambient air to be used in the Modernization Project health risk assessment are discussed below.

1.4.1 Model Selection and Options

The regulatory default mode of the EPA's state-of-the-art regulatory air dispersion model AERMOD (version 12345) ⁴ was used to estimate TAC, PM_{2.5} and CO concentrations at all receptor locations. AERMOD is appropriate for use in estimating ground-level ambient air concentrations resulting from non-reactive buoyant emissions from sources located in simple or complex terrain. This analysis was conducted using AERMOD in the regulatory default mode, which includes the following modeling control options:

- adjusting stack heights for stack-tip downwash,
- using upper-bound concentration estimates for sources influenced by building downwash,
- incorporating the effects of elevated terrain,
- employing the calms processing routine, and
- employing the missing data processing routine.

Air dispersion models such as AERMOD require a variety of inputs such as source parameters (including emission rates), meteorological parameters, topographic information, and receptor parameters.

Operational (Refinery Operations, trucking, and shipping) emissions sources were evaluated in similar but separate air dispersion model runs, due to the temporal difference in the emissions. These models share the same terrain data, meteorological data, and sensitive receptor locations, but differ in source types,

⁴ On November 9, 2005, the EPA promulgated final revisions to the federal Guideline on Air Quality Models, in which they recommended that AERMOD be used for dispersion modeling evaluations of criteria air pollutant and toxic air pollutant emissions from typical industrial facilities. The model can be downloaded at: http://www.epa.gov/scram001/dispersion_prefrec.htm

locations and parameters. The parameters used in the three model runs are described in the sections below.

1.4.2 Modeled Receptor Locations

Receptor locations specify where the model will provide air concentration estimates. Consistent with the BAAQMD's recommendations (BAAQMD, 2012), this analysis estimated TAC concentrations at potential sensitive receptor locations including "people—children, adults, and seniors—occupying or residing in:

- Residential dwellings, including apartments, houses, condominiums;
- Schools, colleges, and universities;
- Daycares;
- Hospitals; and
- Senior-care facilities."

BAAQMD CEQA Guidance (BAAQMD, 2012) requires sensitive receptors within Modernization Project "radius of impact," which is typically 1,000 feet surrounding the Facility boundary to be evaluated. Moreover, the Guidance indicates that locations where "people reside for long periods should [also] be considered sensitive, residential receptors", and should be included in the CEQA analysis. Because of the size and nature of the Modernization Project, the receptors included in this analysis extend beyond the radius of impact and beyond the definition of sensitive receptors indicated in the Guidance. Modeling input files, which include a complete list of the receptors are provided in Attachment 1 and shown in Figure A4.3-HRA-2, and details on modeled receptors are provided below.

1.4.2.1 Coarse Receptor Grid

As shown in Figure A4.3-HRA-2, receptors were modeled at each point defined by a receptor grid with 200 meter by 200 meter spacing ("coarse grid"), on a 12-kilometer by 12-kilometer modeling domain. The type of receptor (e.g., residential or worker) evaluated at each location in the coarse grid was assigned based on land use.

1.4.2.2 Residents

Concentrations at points in a "fine grid" of receptors spaced 50-m apart were modeled over several residential areas in the vicinity of the Facility. The residential communities covered by the fine grids include Point Richmond, Atchison Village, Santa Fe, Iron Triangle, Shields-Reid, central and downtown Richmond, and North Richmond. In addition, potential residential receptors at the Point San Pablo Yacht Harbor are covered by the fine grid. Other residential

Figure A4.3-HRA-2
Chevron Refinery Modernization Project EIR
Modeled Receptor Locations

communities further away from the Facility that are covered or partially covered by the coarse grid include Tara Hills, Parchester Village, El Sobrante, San Pablo, East Richmond, Pinole, El Cerrito, and Albany.

1.4.2.3 Other Sensitive Receptors

Concentrations were also estimated at specific receptor locations to represent surrounding sensitive populations. Sensitive receptors evaluated for this Modernization Project include schools, health care facilities, and care centers for children or the elderly.⁵ Sensitive receptor locations within the 94801 and 94804 zip code areas (in the cities of Richmond, Point Richmond, and San Pablo) were identified from searches of the following sources:

- Schools (public and private) – California Department of Education, California School Directory (CDE, 2013)
- Health Care Facilities – California Office of Statewide Health Planning and Development (OSHPD, 2014)
- Childcare and Elderly Care Centers – California Department of Social Services, Community Care Licensing Division (CCLD, 2012)
- Google Map (<https://www.maps.google.com/>, using keyword of “childcare,” “daycare,” and “school,” to supplement the searches above)

All the identified addresses within 1 mile of the Facility boundary were then geocoded and mapped in the geographic information system. Quality assurance was performed on all geocoded addresses to confirm that mapped locations appear to be the correct facility. The sensitive receptors that were included in the HRA are shown in Table A4.3-HRA-11.

1.4.2.4 Additional Receptors

Other receptors that do not fall under BAAQMD’s definition of sensitive receptors were also included in the risk assessment. Worker receptors at points spaced 50-m apart in a “fine grid” were modeled over several industrial and office areas in the vicinity of the Facility. The industrial areas covered by the fine grid are the on-site San Rafael Rock Quarry close to the southwest corner of the Facility, and the General Chemical Plant, just outside of the east Facility boundary, across Castro Street from the BNSF Richmond Rail Yard. The office park just outside of

⁵ Residential units and worker receptors were identified using Google Map. List of city parks and community centers was provided to ENVIRON by the City of Richmond. Other sensitive receptor locations were obtained from searching various California government licensing departments, supplemented by Google search.

Notes:

1. Locations of sensitive receptors were obtained from the following databases:

(a) Schools (public and private) - California Department of Education, California School Directory (<http://www.cde.ca.gov/re/sd/>)

(b) Health Care Facilities - California Office of Statewide Health Planning and Development (<http://www.oshpd.ca.gov/HID/Products/Listings.html>)

(c) Childcare and Elderly Care Centers - California Department of Social Services, Community Care Licensing Division (http://www.cclid.ca.gov/docs/cclid_search/cclid_search.aspx)

(d) Google Map (<https://www.maps.google.com/>, using keyword of “childcare”, “daycare”, and “school”, to supplement the searches above

(e) Community Centers provided by City of Richmond
2. UTM coordinates are provided in NAD83.

Abbreviations:

UTM: Universal Transverse Mercator
N/A: not available

southeast corner of the Facility boundary, on the north side of the Chevron Way is also covered by the fine grid.

Furthermore, recreational receptors at off-site recreational facilities (i.e., parks) as well as a series of boundary receptors outlining the Facility boundary were included in the model. The boundary receptors were used to estimate acute non-cancer impacts only, which are independent of receptor type.

1.4.2.5 Receptor Modeling Parameter Specifications

In accordance with BAAQMD guidance, a default breathing height of 1.8 meters was used for all receptors. Figure A4.3-HRA-2 presents modeled receptors.

1.4.3 Physical Domain for Health Risk Analysis

The physical scope of the health risk analysis includes sources within the Project site boundary (“on-site sources”). However, only the subset of Modernization Project off-site TAC sources that would impact receptors in the vicinity of the Modernization Project was included in the risk analysis. Thus, the physical extent of off-site emissions included in the TAC inventory for the HRA analysis is smaller than the extent included for the criteria pollutant inventory, as the criteria pollutant inventory extends to the BAAQMD boundary.

Off-site emissions also consist of shipping emissions from ocean going vessels, barges, and tugs within the San Francisco Bay. The emissions estimations from these off-site activities for the TAC inventory included emissions associated with travel of these sources on water during transit, anchorage, and maneuvering. The activities within a radius of approximately 5 nautical miles centered on the Long Wharf were included for the emissions estimations.

1.4.4 Source Types, Locations and Parameters

1.4.4.1 Operations

Operational sources were modeled as point/stack, volume and area sources. Emissions from stacks from process sources, fixed roof tanks, cooling towers and diesel engines were modeled as point sources. Fugitive emissions from floating roof tanks were modeled as circular area sources. Fugitive emissions from process components, such as valves, pumps and flanges in piping were modeled as a rectangular or polygon area sources.

Chevron provided source data for the stacks, floating roof tanks, and non-mobile fugitive sources, in Transmittal #6C. The source parameters used as modeling inputs are presented in Tables A4.3-HRA-12a to d. Information on stack heights and area source release heights provided by Chevron (Chevron

Data Transmittal #6C, 2013) was verified visually using on-line tools (Bing maps, Google Earth), and through consultation with Chevron. The verified source information was then imported into the operational model setup. The locations of point sources, circular sources (modeled storage tanks), flares, and polygon sources (fugitives) are in Figures A4.3-HRA-3 to A4.3-HRA-6, respectively.

Rather than using each of over 100 tank locations as individual sources of emissions, three floating roof tanks T1899, T3100, and T3213, were used for all tank-related emissions in the HRA because of their general representativeness of the entire tank fleet at the Facility, and their proximity to the fenceline and off-site receptors. This resulted in a conservative estimate of impacts from emissions from the tank losses.

Incremental emissions for the stacks, floating roof tanks, and non-mobile fugitive sources were modeled in the HRA. Maximum hourly emissions were assumed to be equal to annual average emissions multiplied by a factor of 2.4, consistent with the BAAQMD Engineering Evaluation for maximum hourly TAC emissions. Incremental emissions allocated for each Refinery Operations source for the Project Crude Blend, 93% Utilization with Maximum Hydrogen Production are found in Attachment 4.

Emissions of the trucking and shipping emissions were modeled for the Baseline Modernization Project scenarios separately, and the risks were based on the difference between the two scenarios.

- **On-Road Vehicles-Running and Idling Emissions (On-Site and Off-Site).** Operational on-road vehicle movement was modeled using a set of consecutive volume sources. The sizing of volume sources varies between road segments such that volume sources visually fit the widths of the roads. All volumes were spaced 50 meters apart. The size and location of the sources are shown in Figures A4.3-HRA-7a through 14b.⁶ Release heights were 4.57 m for delivery trucks, consistent with BAAQMD recommendations for HRAs and land use (BAAQMD, 2010b). The initial vertical dimensions are calculated based on the release height following EPA guidance for an

⁶ In general, the figures with names ended with an “a” shows the vehicle travel paths and source groups; the figures with names ended with a “b” or a “c” shows the actual modeled volume sources. These volume sources are shown as small squares in the figures. The size of the squares represents the width of the roadway segment while the spacing between the squares represents the spacing between the volume sources.

Table A4.3-HRA-12c
Operational Refinery Modeling Source Parameters - Flare Sources
Chevron Modernization Project
Richmond, California

Source Description	Source Group	Source Type	X Coordinates	Y Coordinates	Stack height	Stack temp.	Stack velocity	Heat release	Radiation loss	Notes
					[m]	[K]	[m/s]	[cal/s]	[%]	
H2 FLARE-model as flare S6020	H2FLARE	FLARE	553300	4200001	59.436	1273.15	20	104183.99	55	1,2

Notes:

1. Source group is the names used in the air dispersion modeling.
2. Stack height, stack temperature, stack velocity, stack diameter, and Radiation loss were provided by Chevron.

Abbreviations:

K: Kelvin
m: meter
s: second

		POLYGON	552391	4200498	0	0	1,2
		POLYGON	552321	4200491	0	0	1,2

Notes:

1. Source groups are the names used in the air dispersion modeling. Dispersion factors were generated for each of the source groups separately.
2. The release height and initial vertical dimension were conservatively assumed to be ground level for fugitive sources.

Abbreviations:

m: meter

elevated source not on or adjacent to a building (EPA, 1995).⁷ Initial lateral dimensions are also calculated based on volume size divided by 4.3 following EPA guidance for a single volume source (EPA, 1995).⁸ Details of the source parameters used are presented in Table A4.3-HRA-13.

- **On-Road Vehicles-Idling Emissions.** Area sources were used to represent the delivery truck idling areas on the Modernization Project site. As described above, the idling areas are at the Facility gates. The release height and initial vertical dimensions are consistent with that used for the operational truck movement sources described above. Details of the source parameters used are presented in Table 4.3-HRA-13.

In addition, operational on-road vehicle trips occur both within and outside the Facility boundary. In general, operational trucks travel from highways Interstate 580 (I-580) or Interstate 80 (I-80) to the Facility via Castro Street or Richmond Parkway. Then, some of these trucks enter the Facility through Gate 31 and travel north to the sulfur loading rack area for the sulfur and sodium bisulfide shipments, to the #6 hydrogen sulfide plant for the oxygen shipments, to the liquefied petroleum gas tank truck loading area for the propane shipments, or to the south edge of the No.1 oxidation pond for the solid hazard waste shipments. Some of these trucks enter the Facility through Gate 31 and travel south to the Tally room area for the tally room deliveries and to the Richmond lube oil plant for the lubricant shipment and deliveries. Another portion of these trucks enter the Facility boundary, and immediately turn south to the area for marketing track shipments. Half of the chemical deliveries were assumed to go to the Modernization Project area, while the other half were assumed to go to the Tally room.

1.4.4.1.1 Shipping Emissions

Three types of vessels contribute to the Modernization Project's shipping emissions: ships, barges, and tugs. Depending on the operating mode, these vessels are powered by engines, turbines,⁹ generators, and/or boilers, which can combust a variety of fuels including distillate oil, residual fuel oil, bunker fuel, marine gas oil, and marine diesel oil.

⁷ Initial vertical dimension of elevated volume sources not on or adjacent to a building is release height divided by 4.3.

⁸ Initial lateral dimension of single volume sources is length of side divided by 4.3.

⁹ Gas turbines ships were phased out in 2010 and 2011. Steam turbine SuezMax ships are being replaced in 2014. As a result, no turbine emissions are expected for Baseline and Future cases. The 2008-2010 emissions included that from the turbines.

Notes:

1. Source groups are the names used in the air dispersion modeling. Dispersion factors were generated for each of the source groups separately.
2. ENVIRON used non-adjacent volume sources to model onroad vehicle running emissions.
3. For volume sources, source dimensions were determined by the roadway width where the source is placed. The volume source is placed such that the roadway width is just covered by the volume source.
4. ENVIRON used 50-m spacing between volume sources. Number of sources were determined by the length of the roadway segment.
5. According to USEPA ISC3 User's Guide Volume II, initial vertical dimension of elevated volume sources not on or adjacent to a building is release height divided by 4.3.
6. According to USEPA ISC3 User's Guide Volume II, initial lateral dimension of single volume sources is length of side divided by 4.3.
7. Consistent with BAAQMD recommendations for Health Risk Assessments & Land Use, release height of the modeled volume sources representing truck onroad vehicles was set to 4.57m.
8. ENVIRON used area sources to model onroad vehicle idling emissions.
9. Consistent with BAAQMD recommendations for Health Risk Assessments & Land Use, release height of the modeled area sources representing truck idling was set to 4.57m.
10. According to USEPA ISC3 User's Guide Volume II, initial vertical dimension of elevated area sources is release height divided by 4.3.
11. According to Chevron, half of the chemical delivery trucks go to the Tally room while the other half go to #6 H2S Plant.

There are four operating modes: transiting, maneuvering, anchorage, and at-berth. The list below describes how each Modernization Project source operating in each of the four modes was represented as either a volume or point source in the air dispersion model and Tables A4.3-HRA-14a to 14c.

- Ships, Barges, and Tugs
 - Transiting – Consecutive Volume Sources
 - Maneuvering – Adjacent Volume Sources
 - Anchorage – Single Volume Source
 - At-Berth – Point Sources

Each source type is discussed in detail below.

1.4.4.1.2 Transiting

Transiting emissions occur from vessels moving between ports. Typically, both the main and auxiliary engines operate during transit, and in some cases the vessel's boilers also operate. Modernization Project transiting was modeled as far as approximately 5 nautical miles from the Long Wharf. Figure A4.3-HRA-15 shows the modeled transiting routes within this 5 nautical mile boundary for all Modernization Project sources. Ships, barges, and tugs all travel along the same channels; therefore, all three vessel types were modeled with volume sources in the same spatial locations. The locations of the transit routes were provided by Chevron (Chevron Data Transmittal #26A, 2012). Transiting is divided into six "legs," which were modeled as separate source groups: Leg W, X Northbound, X Southbound, Y, Z Northbound, and Z Southbound.¹⁰ Consecutive volume sources were used to represent vessel transiting emissions along each of these legs. Initial lateral dimensions were calculated based on the width of the volume source following EPA AERMOD guidance for a line source represented by adjacent volume sources.¹¹ Volumes were spaced between 200 and 600 meters apart, depending on the width of the volume sources. Release heights of 28.8, 7.27, and 7.32 meters were used for ships, barges, and tugs, respectively, based on data provided by Chevron (Chevron Data Transmittal #26C (Rev #3), 2014). Initial vertical dimensions were calculated based on the release height following

¹⁰ Moffatt and Nichol calculated emissions separately for each of the six legs; therefore, ENVIRON modeled the six legs as separate source groups.

¹¹ As per the EPA AERMOD User's Guide, the initial lateral dimension of a line source represented by adjacent volume sources is the length of side (which in this case is the width of the channel) divided by 2.15 (EPA, 2004).

Notes:

1. Source groups are the names used in the air dispersion modeling. Dispersion factors were generated for each of the source groups separately.
2. Source dimensions, release heights, and initial vertical dimensions were provided by Chevron.
3. Number of sources were determined by area of each activity's zone and source dimensions for the sources within each zone.
4. According to USEPA ISC3 User's Guide Volume II, initial lateral dimension for line sources represented by adjacent volume sources is length of side divided by 2.15.
5. According to USEPA ISC3 User's Guide Volume II, initial vertical dimension for elevated volume sources (release height >0) not on or adjacent to a building is length of side divided by 4.3.

Abbreviations:

ISC: Industrial Source Complex Model
m: meter
USEPA: United States Environmental Protection Agency

Notes:

1. Source groups are the names used in the air dispersion modeling. Dispersion factors were generated for each of the source groups separately.
2. Source dimensions, release heights, and initial vertical dimensions were provided by Chevron.
3. Number of sources on each transiting route were determined by the length of each transiting route and the source dimensions of the sources on each route.
4. According to USEPA ISC3 User's Guide Volume II, initial lateral dimension for line sources (represented by adjacent volume sources) is length of side divided by 2.15.
5. According to USEPA ISC3 User's Guide Volume II, initial vertical dimension for elevated volume sources (release height >0) not on or adjacent to a building is length of side divided by 4.3.

Figure A4.3-HRA-16
Chevron Refinery Modernization Project EIR
Shipping: Modeled Anchorage and Maneuvering Locations

1.4.4.1.5 At-Berth

At-berth (also known as hoteling) emissions occur when vessels are moored to berths. Typically, only the auxiliary engines, turbines and boilers operate at berth. Figure A4.3-HRA-17 shows the modeled at-berth locations for all Modernization Project sources. There are six berths for vessel mooring, and one station for a stand-by tug. Vessels with diesel generators moor at all six berths. Vessels with boilers moor at berths 1-4, and vessels with turbines¹⁵ moor at berths 1-3. Point sources were used to represent these stationary at-berth emissions. Source locations and release parameters, including stack height, diameter, temperature, and exit velocity were provided by Chevron (Chevron Data Transmittal #26C (Rev #3), 2014). Details of the source parameters used in the air dispersion model are presented in Table A4.3-HRA-14c.

1.4.5 Temporal Variation in Emission Rates

1.4.5.1 Operations (Refinery and Shipping)

To reflect the meteorological conditions when refinery operational emitting activities, on-road mobile source activities and shipping operations (including transiting, maneuvering, anchorage, and operations at berth) are likely to occur, emissions from these sources were all modeled as occurring continuously, i.e., 24 hours per day.

1.4.6 Meteorological Data

AERMOD requires a meteorological input file to characterize the transport and dispersion of pollutants in the atmosphere. In order to create this input file, surface and upper air meteorological data inputs, along with surface parameter data describing the land use and surface characteristics near the Facility, are first processed using AERMET, the meteorological preprocessor to AERMOD. The output file generated by AERMET is the meteorological input file required by AERMOD. Details of AERMET and AERMOD meteorological data needs are described in EPA guidance documents (EPA, 2012a, 2012b). Details of the methodology used for the meteorological data processing for the Modernization Project as well as inputs and outputs of the AERMET runs for both stations can be found in Attachment 2.

Two surface meteorological stations were found in the vicinity of the Facility: one station is maintained by Chevron and is located just south of the western end of the W. Gertrude Avenue (“Gertrude station”). The other station is a National

¹⁵ As indicated by ICF (Chevron Data Transmittal #26F, 2014), vessels with turbines only operate in the 2008-2010 scenario.

EPA AERMOD guidance for an elevated source not on or adjacent to a building.¹² Emissions were distributed uniformly amongst all volume sources within a given leg. Details of the source parameters used in the air dispersion model are presented in Table A4.3-HRA-14b.

1.4.4.1.3 Maneuvering

Maneuvering emissions occur when vessels operate at slow speeds in-port, such as approaching berth. Typically, the main engine, auxiliary engines, and boilers all operate during maneuvering, though the main engine operates at lower loads than it would during transit. Figure A4.3-HRA-16 shows the modeled areas of maneuvering. Barges and tugs all maneuver in the same areas southwest and northeast of the wharf; therefore, these vessel types were modeled with volume sources in the same spatial locations. Ships only maneuver in the area southeast of the wharf. These maneuvering locations were provided by Chevron. Twenty adjacent volume sources were used to represent vessel maneuvering emissions. Initial lateral dimensions were calculated by dividing the length of side by 4.3, which is typical for large areas of emissions represented by adjacent volume sources. The release heights and initial vertical dimensions were identical to those used in Transiting. Emissions were distributed uniformly amongst all volume sources within the maneuvering area. Details of the source parameters used in the air dispersion model are presented in Table A4.3-HRA-14a.

1.4.4.1.4 Anchorage

Anchorage emissions occur from vessels temporarily at anchor at sea, outside of the port. Typically, only the auxiliary engines and boilers operate at anchorage. Figure A4.3-HRA-16 shows the modeled anchorage location for all Modernization Project sources. Ships and barges¹³ anchor at the same location; therefore, these vessel types were modeled in the same spatial location. The anchorage location was provided by Chevron (Chevron Data Transmittal #26F, 2014). A single volume source was used to represent anchorage emissions. The initial lateral dimension was calculated based on the width of the volume source, following EPA AERMOD guidance for a single volume source.¹⁴ The release heights and initial vertical dimensions were identical to those used in Transiting. Details of the source parameters used in the air dispersion model are presented in Table A4.3-HRA-14a.

¹² As per the EPA AERMOD User's Guide, the initial vertical dimension of an elevated source not on or adjacent to a building is the vertical dimension of the source divided by 4.3 (EPA, 2004).

¹³ Tugs do not set anchor.

¹⁴ As per the EPA AERMOD User's Guide, the initial lateral dimension of a single volume source is the length of side divided by 4.3 (EPA, 2004).

Averaging Time (AT)	[days]	25550	25550	25550	25550	25550	25550	25550	25550
Intake Factor, Inhalation (IF _{inh})	[m ³ /kg-day]	0.29	0.057	0.015	0.014	0.0043	0.0083	0.0035	0.014

Notes:

- Exposure parameters reflect default values for residents from BAAQMD 2010.
- Exposure parameters reflect default values for workers from BAAQMD 2010. The daily breathing rate for a worker corresponds to an hourly breathing rate of 1.3 m³/hour for eight hours.
- Exposure parameters reflect default values for students from BAAQMD 2010.
- Daily breathing rates for day care child receptors reflect default breathing rates from BAAQMD 2010. The day care centers were assumed to operate 10 hours per day from 7 AM to 5 PM. The day care child receptor was assumed to be at a day care center while the parents are at work; 245 days reflects the default exposure frequency for a worker from BAAQMD 2010. It was assumed that a day care center would accept children from 6 weeks to 6 years old.
- Adult patient was assumed to be 16 years old and above, and stay in hospital for the whole year. Daily breathing rate and exposure time for adult patients reflect default values for resident adults from BAAQMD 2010.
- Child patient was assumed to be in hospital for the whole year. Daily breathing rate and exposure time for child patients reflect default values for resident children from BAAQMD 2010.
- Hourly breathing rates for recreational user receptors reflect recommended mean breathing rates based on moderate activities for short-term exposures for age groups from birth to 70 years from USEPA 2011. The recreational user receptors were conservatively assumed to be at a recreational location 1 hours per day, once a week, every week (52 weeks) of the year.
- For the child receptors at community center, the exposure parameters were conservatively assumed to be the same as those for day care child.

Equations:

Resident, Worker, School Child, Daycare Child, Community Center Child, and Patient:

$$IF_{inh} = DBR * ET * EF * ED * CF1 / AT$$

$$CF1 = 0.001 \text{ (m}^3\text{/L)}$$

Recreational User:

$$IF_{inh} = HBR * ET * EF * ED * CF2 / \text{Body Weight} / AT$$

Where: Body Weight_{adult} = 63 kg (Cal/EPA 2003)

$$CF2 = 24 \text{ hours/day}$$

Figure A4.3-HRA-17
Chevron Refinery Modernization Project EIR
Shipping: Modeled Point Source Locations

Climate Data Center (NCDC) station (AWS ID 994036), located on the Refinery Pier just south of I-580 (“Wharf station”). Between these two stations lies a mountain ridge that extends in the southeast direction from Point San Pablo. Based on an evaluation of the wind patterns from these two stations, conditions at the Gertrude station are more representative of the majority of the Facility area (north and east of the mountain ridge), while conditions the Wharf station are more representative of the Facility area to the south and west of the mountain ridge.

Therefore, both datasets were processed using AERMET version 12345. The data from October 1, 2009 to September 30, 2010 for each station were processed to ensure the 90% completeness criteria required by EPA is met (40 CFR Part 51).¹⁶ The two on-site surface air stations, together with the surface pressure and cloud cover data from Oakland International Airport surface station, and upper air data from the Oakland International Airport upper air station, were used in the processing.

1.4.6.1 Operations

Dispersion of emissions from Facility sources and from operational mobile on-road sources located north and east of the mountain ridge was modeled using the Gertrude station meteorological data, while the Wharf meteorological data were used to model dispersion from Refinery Operations (i.e., tanks T1899 and T3100) located south and west of the mountain ridge. No operational on-road mobile sources are located south and west of the mountain ridge.

Because shipping operations occur along the Long Wharf and in the water south and west of the mountain ridge (with the exception of the northern sections of two shipping transit legs that run north of Point San Pablo), AERMOD-ready meteorological data processed for the Wharf station were used for air dispersion modeling of shipping emissions.

1.4.7 Terrain

AERMOD uses a terrain preprocessor, AERMAP version 11103,¹⁷ to determine elevations of the surrounding landscape. Data from the National Elevation Data (NED) set, available from the United States Geological Survey,¹⁸ were utilized to

¹⁶ More information on meteorological data processing performed for this analysis is presented in Attachment 2.

¹⁷ More information on the model and the executable is available at: http://www.epa.gov/ttn/scram/dispersion_related.htm.

¹⁸ NED data available at: <http://seamless.usgs.gov/website/seamless/viewer.htm>.

import the elevation information for sources and receptors. AERMAP was used to extract elevations from the NED dataset. NED 1/3 arc-second data do not provide sufficient resolution in elevations for the mountain ridge area near the Modernization Project site, where some of the modeled worker receptors are located. Although the higher resolution NED 1/9 arc-second data set does provide sufficient resolution for these receptors, it does not have elevation information over water. To ensure sufficient resolution and coverage for receptor elevations for the AERMAP run, NED 1/9 arc-second data were used, supplemented by the 1/3 arc-second data for water areas.

1.4.7.1 Rural or Urban Boundary Layer Options

An important consideration in an air dispersion modeling analysis is the selection of rural or urban dispersion coefficients, which are influenced by the level of development (i.e., height of buildings and urban heat island effect) in the vicinity of the Modernization Project. Due to the proximity of the project to open water (which has no buildings or any heat generating sources), the models use rural dispersion coefficients, which is consistent with EPA guidance (EPA, 2009).

1.4.8 Model Averaging Periods and Unit Emissions Dispersion Factor Method

Calculation of chemical concentrations for use in exposure analysis requires the selection of appropriate concentration averaging times. In accordance with OEHHA guidance (OEHHA, 2003), annual average concentrations were estimated and used to evaluate cancer risk, chronic non-cancer and PM_{2.5} impacts. Acute non-cancer impacts were estimated using the maximum 1-hr concentration. CO concentrations were estimated for 1-hour and 8-hour averaging periods.

Operational emissions were modeled using the unit emissions dispersion factor method, such that emission source groups are input to the model with unit average annual emission rates (i.e., 1 gram per second [g/s]), and the model estimates 1-hour maximum or annual average dispersion factors (with units of [µg/m³]/[g/s]). To calculate annual average ambient air concentrations, the annual average dispersion factors were multiplied by the annual emission rates. Details on the database used to estimate health impacts are contained in Attachment 3.

For acute non-cancer hazard analyses, the estimated 1-hour maximum dispersion factors for each source group were used. These dispersion factors were multiplied by the maximum 1-hour emission rate to determine the maximum 1-hour concentration for a given source group. Note that because the maximum emissions for each group are not expected to occur during the same hour of the year, summing the maximum 1-hour concentrations across all source

groups yields conservative (i.e., overestimates of) total air concentrations. Attachment contains the database inputs that were used to combine 1-hour maximum dispersion factors and actual emission rates to yield 1-hour air concentrations and to conduct further acute non-cancer hazard calculation. A similar method was used to estimate the short term CO concentrations.

The dispersion factors by source group for the MEIs, as well as the TAC emission rate for refinery, shipping and trucking are presented in Attachment 4.

1.4.9 Buildings

Turbulent eddies can form on the downwind side of buildings, and may cause a plume from a stack or point source located near the building to be drawn towards the ground to a greater degree than if the building were not present. This is referred to as the building downwash effect. The effect can increase the resulting ground-level pollutant concentrations downwind of a building. ENVIRON used the dimensions and locations of nearby buildings, to allow AERMOD to incorporate algorithms to evaluate the downwash effect on stack sources.

There are several Refinery Operations point sources located near buildings that could potentially cause downwash effects. In addition, dispersion of emissions from shipping point sources such as generators, boilers, and turbines¹⁹ aboard moored vessels at berth may be influenced by the Refinery Pier, Long Wharf, and buildings located on top of the Long Wharf. Thus, buildings and structures near operational point sources were included in the dispersion model in order to evaluate downwash effects. The coordinate and building height data provided by Chevron (Chevron Data Transmittal #6C, 2013) were verified visually using on-line tools (Bing maps, Google Earth), and through consultation with Chevron. Buildings included in the Shipping model are in Figure A4.3-HRA-18, and buildings included in the Refinery Operations model are in Figure A4.3-HRA-19. The building dimensions are also described in Tables A4.3-HRA-12e and 14d.

1.4.10 Model Adjustment Factors

Cal/EPA recommends applying an adjustment factor to air concentrations based on a continuous averaging period (i.e., 24 hours per day, 365 days per year) when the following three things are true: (1) the actual exposure occurs for less than 24 hours per day and/or less than 1 year; (2) emission activities occur for less than 24 hours per day and/or less than 1 year; and (3) exposures are entirely or partially concurrent with emitting activities (OEHHA, 2003). The model

¹⁹ As indicated by ICF (Chevron Data Transmittal #26F, 2014), vessels with turbines only operate in the 2008-2010 scenario.

Chevron Refinery Modernization Project EIR
Modeled Refinery Buildings

averages the emissions over 24 hour per day over a year. The modeling adjustment factor is applied to the modeled annual average concentrations to reflect the fact that the actual exposure concentration the receptor is exposed to is higher than the average annual concentration.

1.4.10.1 Operations

Because operational activities occur at any time of day, a constant emission rate for 24 hours per day, 7 days per week was assumed for all operational sources. Therefore, no MAF was required for any receptor type.

1.5 HEALTH EFFECT CHARACTERIZATION METHODS

The following sections discuss the various components required for conducting this risk assessment in detail. Attachment 3 contains a description of SARAD, the Microsoft Access databases that were used to calculate air concentrations and to conduct further health risk estimations based on the methodology described below. SARAD databases mimic the calculation method used in the CARB Hotspots Analysis Reporting Program (HARP) and its On-Ramp extension. Attachment 3 describes in detail on how these databases works and the equivalency tests conducted to prove that the SARAD databases and HARP will generate same risk values when using the same inputs.

1.5.1 Exposure Assessment

1.5.1.1 Exposed Populations

As described earlier, the potentially exposed populations²⁰ evaluated in this assessment are:

- Residents (children and adults)
- School children
- Daycare children
- Community center children and adults
- Patient children and adults
- Recreational facility children and adults
- Adult workers

A maximum exposed individual sensitive receptor (MEISR) is identified as the sensitive receptor (among all of the potential exposed sensitive populations) with

²⁰ Although neither recreational adult or children nor workers are sensitive receptors under BAAQMD guidance, these receptors were included for completeness. Therefore the MEISR location includes recreational users and worker locations.

the highest estimated cancer risk, chronic non-cancer impact, or acute non-cancer health impact. In addition, a MEISR is also identified for the PM_{2.5} concentration. In order to identify the MEISR for each health impact, the impacts were calculated for all receptors in the modeling domain.²¹

In addition, a set of boundary receptors was also included in the model. Note that because no sensitive populations will reside at the boundary receptor locations for long periods, they would not experience chronic exposure; therefore, these boundary receptors were included for acute health impact analysis only.

The exposure parameters used for estimating excess lifetime cancer risks for all potentially exposed populations were obtained using risk assessment guidelines from OEHHA (2003) and BAAQMD (2010a), unless otherwise noted, and are presented in Tables A4.3-HRA-15. These exposure parameters are included in Attachment 3 for the risk calculation.

1.5.1.2 Operations

All receptor populations evaluated in this analysis were assumed to be exposed to operational emissions. The exposure parameters used for estimating excess lifetime cancer risks for all potentially exposed populations are presented in Table A4.3-HRA-15.

1.5.1.3 Calculation of Intake

The dose estimated for each exposure pathway is a function of the concentration of a chemical and the intake of that chemical.

The intake factor for inhalation, IF_{inh}, can be calculated as follows:

$$IF_{inh} = \frac{DBR * ET * EF * ED * CF}{AT}$$

Where:

$$IF_{inh} = \text{Intake Factor for Inhalation (m}^3\text{/kg-day)}$$

²¹ The only exception is shipping, for which 70-year age-specific sensitivity factors (ASF) weighted emissions provided by ICF (Chevron Data Transmittal #26F, 2014) were used. Health impacts for only residential and worker receptors were evaluated. Using the 70-year ASF weighted emissions for worker receptors were a conservative approach. In addition, health impacts to the 70-year residents are expected to be higher than that of the other populations.

DBR	=	Daily Breathing Rate (L/kg-day)
ET	=	Exposure Time (hours/24 hours)
EF	=	Exposure Frequency (days/year)
ED	=	Exposure Duration (years)
AT	=	Averaging Time (days)
CF	=	Conversion Factor, 0.001 (m ³ /L)

The chemical intake or dose is estimated by multiplying the inhalation intake factor, IF_{inh} , by the chemical concentration in the air, C_i . This calculation is based on the dose algorithm given in Office of Environmental Health Hazard Assessment (OEHHA) Hot Spots guidance (OEHHA, 2003).

1.5.2 Toxicity Assessment

The toxicity assessment characterizes the relationship between the magnitude of exposure and the nature and magnitude of adverse health effects that may result from such exposure. For purposes of calculating exposure criteria to be used in risk assessments, adverse health effects are classified into two broad categories – cancer and non-cancer endpoints. Toxicity values used to estimate the likelihood of adverse effects occurring in humans at different exposure levels are identified as part of the toxicity assessment component of a risk assessment.

All chemicals emitted from operations that were identified in the BAAQMD Regulation 2 Rule 5 were included in this analysis. Diesel exhaust, a complex mixture that includes hundreds of individual constituents, is identified by the State of California as a known carcinogen. Under California regulatory guidelines, DPM is used as a surrogate measure of carcinogen exposure for the mixture of chemicals that make up diesel exhaust as a whole. There is currently no acute non-cancer toxicity value available for DPM. Thus, no acute health impacts were calculated for diesel equipment operations in this evaluation. Besides DPM, 56 other TACs were also evaluated in this HRA. The chemicals and the toxicity values for the chemicals evaluated in this analysis are summarized in Table A4.3-HRA-1 and described below.

1.5.3 Operations

Human health impacts from Modernization Project operations are based on the TAC emissions from stationary sources, on-road mobile sources, and shipping marine vessels.

Table A4.3-HRA-15
Exposure Assumptions - Operations
Chevron Modernization Project
Richmond, California

Exposure Parameter	Units	Resident ¹	Worker ²	School Child ³	Daycare Child ⁴	Adult Patient ⁵	Child Patient ⁶	Recreational User ⁷	Community Center Child ⁸
Daily Breathing Rate (DBR)	[L/kg-day]	302	149	581	581	302	581	--	581
Hourly Breathing Rate (HBR)	[m ³ /hour]	--	--	--	--	--	--	1.56	--
Exposure Time (ET)	hours/24 hours	24	8	10	10	24	24	1	10
Exposure Frequency (EF)	[days/year]	350	245	180	245	365	365	52	245
Exposure Duration (ED)	[years]	70	40	9.0	5.9	1.0	1.0	70	5.9
Averaging Time (AT)	[days]	25550	25550	25550	25550	25550	25550	25550	25550
Intake Factor, Inhalation (IF _{inh})	[m ³ /kg-day]	0.29	0.057	0.015	0.014	0.0043	0.0083	0.0035	0.014

Notes:

- Exposure parameters reflect default values for residents from BAAQMD 2010.
- Exposure parameters reflect default values for workers from BAAQMD 2010. The daily breathing rate for a worker corresponds to an hourly breathing rate of 1.3 m³/hour for eight hours.
- Exposure parameters reflect default values for students from BAAQMD 2010.
- Daily breathing rates for day care child receptors reflect default breathing rates from BAAQMD 2010. The day care centers were assumed to operate 10 hours per day from 7 AM to 5 PM. The day care child receptor was assumed to be at a day care center while the parents are at work; 245 days reflects the default exposure frequency for a worker from BAAQMD 2010. It was assumed that a day care center would accept children from 6 weeks to 6 years old.
- Adult patient was assumed to be 16 years old and above, and stay in hospital for the whole year. Daily breathing rate and exposure time for adult patients reflect default values for resident adults from BAAQMD 2010.
- Child patient was assumed to be in hospital for the whole year. Daily breathing rate and exposure time for child patients reflect default values for resident children from BAAQMD 2010.
- Hourly breathing rates for recreational user receptors reflect recommended mean breathing rates based on moderate activities for short-term exposures for age groups from birth to 70 years from USEPA 2011. The recreational user receptors were conservatively assumed to be at a recreational location 1 hours per day, once a week, every week (52 weeks) of the year.
- For the child receptors at community center, the exposure parameters were conservatively assumed to be the same as those for day care child.

Equations:

Resident, Worker, School Child, Daycare Child, Community Center Child, and Patient:

$$IF_{inh} = DBR * ET * EF * ED * CF1 / AT$$

$$CF1 = 0.001 \text{ (m}^3\text{/L)}$$

Recreational User:

$$IF_{inh} = HBR * ET * EF * ED * CF2 / \text{Body Weight} / AT$$

Where: Body Weight_{adult} = 63 kg (Cal/EPA 2003)

$$CF2 = 24 \text{ hours/day}$$

Abbreviations:

BAAQMD = Bay Area Air Quality Management District

Cal/EPA = California Environmental Protection Agency

kg = kilogram

L = Liter

m³ = cubic meters

USEPA = US Environmental Protection Agency

United States Environmental Protection Agency (USEPA), 2011. *Exposure Factors Handbook: 2011 Edition*. Table 6-2. September.

1.5.3.1 On-Road Mobile Sources

Cancer risk and chronic non-cancer hazard associated with on-road mobile sources are based on DPM concentrations from on-road diesel trucks. As discussed in *Appendix 4.3-TRANS*, all operational trucks are assumed to be diesel-fueled.

1.5.3.2 Shipping Sources

Consistent with direction from the BAAQMD, emissions from internal combustion engines, regardless of fuel used (diesel, heavy fuel oil, etc.) were characterized using the same emission factors and speciation profiles as those for diesel combustion. Shipping emissions from boilers were characterized using CARB profile 504 for reactive organic gases and a conservative²² hybrid profile for PM₁₀ that combines EPA profile 127102.5 (external combustion boilers on distillate or residual fuel oil) and EPA profile 5676 (Crude oil tanker at sea).

1.5.3.3 Refinery Operations Sources

Cancer risk, chronic non-cancer hazard, and acute non-cancer hazard associated with the stationary source operation are based on the TACs emitted through fuel combustion, material processing, and other miscellaneous emission sources.

1.6 CANCER RISK ADJUSTMENT FACTOR

The BAAQMD recommends estimation of cancer risk using methods from OEHHA's Technical Support Document for Cancer Potency Factors: Methodologies for Derivation, Listing of Available Values, and Adjustment to Allow for Early Life Stage Exposures (Cal/EPA, 2009). The OEHHA Technical Support Document proposes the use of age-specific sensitivity factors to account for an "anticipated sensitivity to carcinogens" of infants and children. Under the revised approach, cancer risk estimates are weighted by a factor of 10 for exposures that occur from the third trimester of pregnancy to 2 years of age and by a factor of 3 for exposures that occur from 2 years to 16 years of age. The cancer risk adjustment factor (CRAF) is the weighted factor over the entire exposure duration.

1.6.1 Operations

Cancer risks associated with operations were adjusted using CRAFs for the following receptors: 70-year lifetime resident, daycare child, community center

²² A conservative hybrid profile was created by using all profile constituents from both profiles, and choosing the greater fraction of constituent when both profiles had a specific constituent.

child, school child, patient child, and lifetime recreational user. The BAAQMD-recommended CRAF for a 70-year resident of 1.7 was applied to the cancer risk estimation for a lifetime resident and a lifetime recreational user.²³ All adult populations (i.e., adult patient and adult worker) were assumed to be over 16 years old; therefore, no weighting factor was applied in the cancer risks estimations for these populations. These factors are summarized in Table A4.3-HRA-16.

1.6.2 Health Effects

1.6.2.1 Estimation of Cancer Risks

Excess lifetime cancer risks are estimated as the upper-bound incremental probability that an individual will develop cancer over a lifetime as a direct result of exposure to potential carcinogens. The estimated risk is expressed as a unitless probability. The cancer risk attributed to a chemical is calculated by multiplying the chemical intake or dose at the human exchange boundaries (e.g., lungs) by the chemical-specific cancer potency factor (CPF). The equation used to calculate the potential excess lifetime cancer risk for the inhalation pathway is as follows:

$$\text{Risk}_{\text{inh}} = \sum C_i \times CF \times \text{IF}_{\text{inh}} \times \text{CPF}_i \times \text{CRAF}$$

Where:

Risk_{inh}	=	Cancer Risk; the incremental probability of an individual developing cancer as a result of inhalation exposure to a particular potential carcinogen (unitless)
C_i	=	Annual Average Air Concentration for Chemical _i ($\mu\text{g}/\text{m}^3$)
CF	=	Conversion Factor ($\text{mg}/\mu\text{g}$)
IF_{inh}	=	Intake Factor for Inhalation ($\text{m}^3/\text{kg}\cdot\text{day}$)
CPF_i	=	Cancer Potency Factor for Chemical _i ($\text{mg chemical}/\text{kg body weight}\cdot\text{day})^{-1}$
CRAF	=	Cancer Risk Adjustment Factor (unitless)

²³ The only exception is shipping, for which 70-year ASF weighted emissions provided by ICF (Chevron Data Transmittal #26F, 2014) were used. As a result, no additional CRAF was applied for the residential receptors.

Table A4.3-HRA-16
Cancer Risk Adjustment Factors - Operations
Chevron Modernization Project
Richmond, California

Receptor	Cancer Risk Adjustment Factorsr (CRAF)	Note
Resident	1.7	a, b
Worker	1	a, c
School Child	3	a, d
Day Care Child	5.2	a, e
Adult Patient	1	a, f
Child Patient	10	a, g
Recreational User	1.7	a, h
Community Center Child	5.2	a, i

Notes:

- a. Based on BAAQMD 2010.
- b. A resident was assumed to be exposed for the whole lifetime.
- c. A worker was assumed to represent age 16 to age 70 years.
- d. A school child was assumed to be from 7 years old to 16 years old.
- e. Daycare centers were conservatively assumed to accept children from 6 weeks to 6 years old.
- f. An adult patient was assumed to be 16 years older and above.□
- g. A child patient was assumed to represent age third trimester to 2 years.□
- h. A recreational user was assumed to be exposed for the whole lifetime.□
- j. Community centers were conservatively assumed to accept children from 6 weeks to 6 years old.

1.6.2.2 Estimation of Chronic Non-cancer Hazard Quotients/Indices

The potential for exposure to result in chronic non-cancer effects is evaluated by comparing the estimated annual average air concentration (which is equivalent to the average daily air concentration) to the chemical-specific non-cancer chronic reference exposure levels (RELs). When calculated for a single chemical, the comparison yields a ratio termed a hazard quotient or HQ. To evaluate the potential for adverse chronic non-cancer health effects from simultaneous exposure to multiple chemicals, the HQs for all chemicals are summed, yielding an HI.

The equations used to calculate the chemical-specific HQs and the overall HI are:

$$\text{Chronic HQ}_i = C_i / \text{cREL}_i$$

$$\text{Chronic HI} = \sum \text{HQ}_i$$

Where:

Chronic HQ_i = Chronic Hazard Quotient for Chemical_i
(unitless)

Chronic HI = Hazard Index (unitless)

C_i = Annual Average Air Concentration for
Chemical_i (µg/m³)

cREL_i = Chronic Non-cancer Reference Exposure
Level for Chemical_i (µg/m³)

1.6.2.3 Estimation of Acute Non-cancer Hazard Quotients/Indices

The potential for exposure to result in acute non-cancer effects is evaluated by comparing the estimated 1-hour maximum air concentration to the chemical-specific non-cancer acute RELs. The estimation method for determining the 1-hour maximum concentration was described in the “Air Dispersion Modeling” section. When calculated for a single chemical, the comparison yields a ratio termed a hazard quotient or HQ. To evaluate the potential for adverse acute non-cancer health effects from simultaneous exposure to multiple chemicals, the HQs for all chemicals are summed, yielding an HI.

The equations used to calculate the chemical-specific HQs and the overall HI are:

$$\text{Acute HQ}_i = C_i / \text{aREL}_i$$

$$\text{Acute HI} = \sum \text{HQ}_i$$

Where:

Acute HQ_i	=	Acute Hazard Quotient for Chemical _i (unitless)
Acute HI	=	Hazard Index (unitless)
C_i	=	1-hour Maximum Air Concentration for Chemical _i ($\mu\text{g}/\text{m}^3$)
$aREL_i$	=	Acute Non-cancer Reference Exposure Level for Chemical _i ($\mu\text{g}/\text{m}^3$)

1.7 SUMMARY OF RESULTS

Tables A4.3-HRA-17a and b summarizes the cancer risk, chronic HI, $PM_{2.5}$ concentration, and acute HI impact at the off-site MEISR for the total, and for operational trucking, shipping, and Refinery Operations sources. Tables A4.3-HRA 18a-k show the highest contributing sources to the health impacts for each type of health impact each for Refinery Operations, shipping and trucking. These tables also show the reductions in health impacts that result from reductions in emissions of certain TACs as a result of the Modernization Project. These reductions are highlighted in the tables in blue. The listed percentages are the percent of the total increase or decrease, respectively.

Figures A4.3-HRA-20 to 35 present cancer risks, chronic HIs, $PM_{2.5}$ concentrations, and acute HIs at all modeled receptors and MEISRs from the combination of Refinery Operations, shipping and trucking for the four cases evaluated in this HRA.²⁴ Figures A4.3-HRA-36 to -59, presents cancer risks, chronic HIs, $PM_{2.5}$ concentrations and acute HIs at all modeled receptors each for the Refinery Operations, shipping and trucking for the 93% Utilization cases with Project Design Features.

1.7.1 Cancer Risks

The incremental excess cancer risk for the mitigated Project case is 4.0 in 1 million at the MEI. The excess lifetime cancer risk for carcinogenic compounds is calculated for those compounds considered by Cal/EPA to pose a carcinogenic risk to humans. This value represents the risk, or theoretical probability, of developing cancer from that chemical upon exposure to that medium. A cancer

²⁴ These figures are based on the analysis for the inhalation pathway because as described in Section 1.3, the cancer risks and non-cancer hazards associated with the multi-pathway exposures are small compared to the thresholds for cancer risks and non-cancer chronic hazards.

risk of one in one million means that in a population of one million people, not more than one additional person would be expected to develop cancer as the result of the exposure to the substance causing that risk.

As is shown in Table A4.3-HRA-17, the majority of the incremental risk comes from shipping activities, followed by Refinery Operations and trucking. The MEI is located in Point Richmond, near the Long Wharf as shown in Figure A4.3-HRA-20. DPM, emitted from the marine vessels, is the main risk driver. Risks at the MEI from shipping is 3.4 in 1 million at the berths. The risks at the MEI also represent the greatest shipping risks at any location. The shipping project design feature of replacing the PAL vessels' auxiliary engines with turbogenerators reduce the risks at the berth, as turbogenerators do not emit DPM. Risks at the MEI from Refinery Operations are 0.4 in 1 million and is also located in Point Richmond. Finally, risks from trucking emissions at the MEI are 0.1 in 1 million, and are driven by DPM emissions from trucking. The greatest risks from trucking are located near a truck on ramp distant from the MEI. These risks are overestimated, because the decrease in DPM emissions that result from increasing future regulation were not considered in this assessment.

1.7.2 Chronic Hazard Index

The incremental excess chronic HI for the mitigated Project case is 0.02 at the MEI, which is a worker receptor.²⁵ The maximally exposed residential receptor has a chronic HI far less than this value. This is well below the BAAQMD CEQA threshold of 1.0 for chronic HI, and below the de minimis threshold for No Net Increase of risk of 0.2. The HI represents the sum of the HQs developed for each individual chemical. The HQ is the ratio of the estimated dose from exposure to a compound in a medium, to a value that is believed not to produce adverse health effects for each chemical considered. The HQ is calculated for all compounds, carcinogenic as well as non-carcinogenic. This value is a measure of the non-carcinogenic toxicity of a compound; it is not a probability. Estimated HQs and HIs are expressed using decimal notation (e.g., 0.001). A value below 1.0 is believed to not cause adverse health impacts.

As is shown in Table A4.3-HRA-17, the majority of the incremental HI comes from diethanolamine and sulfur from the SRUs and the TKC. The MEI is located in Point Molate, to the east of the Refinery Operations. The HI at the MEI from shipping is 0.002 at the MEI, and results from DPM emitted from shipping activities. The HI from shipping is the greatest in Point Richmond, but is still

²⁵ The maximum non-cancer chronic hazard index considering all pathways is 0.1, still well below the CEQA threshold and NNI.

Notes:

1. The excess lifetime cancer risk assumes that an individual adjacent to the refinery operation activity is exposed to emissions from trucking, shipping, and refinery sources. Cancer risks are estimated as the upper-bound incremental probability that an individual will develop cancer over a lifetime as a direct result of exposure to potential carcinogens. The estimated risk is expressed as a unitless probability. The cancer risks attributed to the TAC emissions associated with the Project were calculated based on the TAC exposure point concentration (C), the intake factors presented in Tables AQ-HRA-6c, the CPF presented in Table AQ-HRA-7, and the ASFs presented in Table AQ-HRA-8c.

Calculation:

$$Risk_{inh} = \sum (C_i \times MAF \times CF \times IF_{inh} \times CPF_i \times ASF)$$

Where:

- Risk_{inh} = Cancer Risk; the incremental probability of an individual developing cancer as a result of inhalation exposure to a particular potential carcinogen (unitless)
- C_i = Modeled Annual Average Concentration in air for Chemical I (µg/m³)
- MAF = Modeling Adjustment Factor
- CF = Conversion Factor (mg/µg)
- IF_{inh} = Intake Factor for Inhalation (m³/kg-day)
- CPF_i = Cancer Potency Factor for Chemical I (mg chemical/kg body weight-day)
- ASF = Age Sensitivity Factor

2. The potential for exposure to result in chronic noncancer effects is evaluated by comparing the estimated annual average air concentration (which is equivalent to the average daily air concentration) to the chemical-specific noncancer chronic RELs. When calculated for a single chemical, the comparison yields a ratio termed a hazard quotient. The hazard quotients were then summed for all chemicals to yield the hazard index. The hazard quotients were calculated based on the modeled annual average TAC concentrations and the chronic REL presented in Table AQ-HRA-8.

Calculation:

$$HQ_i = C_i / REL_i; HI = \sum HQ_i$$

Where:

- HI = Hazard Index
- HQ_i = Hazard Quotient for Chemical I
- C = Average Daily Air Concentration for Chemical I (µg/m³)
- REL_i = Noncancer Reference Exposure Level for Chemical I (µg/m³)

3. The MEISR is the offsite receptor location with the maximum annual average PM_{2.5} concentration from the modeled operational sources. The PM_{2.5} concentration takes into account emissions from trucking, shipping, and refinery sources.

4. ENVIRON evaluated the acute hazard indices (HIs) for the maximum hourly emissions scenarios. The potential for exposure to result in acute noncancer effects is evaluated by comparing the estimated maximum hourly air concentration to the chemical-specific noncancer acute RELs. When calculated for a single chemical, the comparison yields a ratio termed a hazard quotient. The acute HI is calculated by summing all hazard quotients.

Calculation:

$$Acute\ HI = \sum Acute\ HQ_i = \sum C_i / REL_i$$

Where:

- Acute HI = Acute Hazard Index
- Acute HQ_i = Acute Hazard Quotient for Chemical i
- C_i = Max hourly Air Concentration for Chemical i (µg/m3)
- REL_i = Noncancer Reference Exposure Level for Chemical i (µg/m3)

Abbreviations:

- µg: microgram
- CPF: Cancer Potency Factor
- HQ: Hazard Quotient
- HI: Hazard Index
- kg: kilogram
- m: meter
- MEISR: Maximally Exposed Individual Sensitive Receptor
- PDF: Project Design Feature
- REL: Reference Exposure Level
- TAC: Toxic Air Contaminants
- UTM: Universal Transverse Mercator

below the very low level of 0.02. The HI from trucking at the MEI is less than 0.001, and results from DPM emissions. The greatest HI from trucking is located at a freeway onramp, and is still less than the very low value of 0.02.

1.7.3 Acute Hazard Index

The incremental excess acute hazard for the mitigated Project case is 0.5 at the MEI, which is a boundary receptor between the Facility and Point Molate. Although no one lives there, an individual could be present for an hour, which is the averaging duration for acute effects. This is below the BAAQMD CEQA significance threshold of 1.0 for acute non-cancer health effects. The HI represents the sum of the HQs developed for each individual chemical. The HQ is the ratio of the estimated dose from exposure to a compound in a medium, to a value that is believed not to produce adverse health effects for each chemical considered. The HQ is calculated for all compounds, carcinogenic as well as non-carcinogenic. This value is a measure of the non-carcinogenic toxicity of a compound; it is not a probability. Estimated HQs and HIs are expressed using decimal notation (e.g., 0.001). A value below 1.0 is believed to not cause adverse health impacts.

The maximally exposed residential receptor has an acute HI of 0.2, and is located in Point Richmond. These values are below the BAAQMD CEQA significance threshold of 1.0 for acute HI, and the residential receptor is at the de minimis threshold for No Net Increase of risk of 0.2.

More than 80% of the acute HI of 0.2 results from hydrogen sulfide concentrations at the residential MEI. The REL for hydrogen sulfide, which is the basis for the level at which no adverse health impacts is expected to occur, is based on the California Ambient Air Quality Standard (CAAQS) for hydrogen sulfide of 0.03 parts per million (ppm). According to OEHHA (2000), "The standard [CAAQS] was adopted in 1969 and was based on the geometric mean odor threshold measured in adults. The purpose of the standard was to decrease odor annoyance. The standard was reviewed in 1980 and 1984 (CARB, 1984), and was not changed since no new relevant information had emerged." Therefore, the REL was set to reduce odor annoyance, rather than to minimize health effects. OEHHA (2008) also notes, that "[a]t the current CAAQS of 0.03 ppm, the level would be detectable by 83% of the population and would be discomforting to 40% of the population", and goes on to state that, "[t]he World Health Organization reports that in order to avoid substantial complaints about odor annoyance among the exposed population, hydrogen sulfide concentrations should not be allowed to exceed 0.005 ppm (7 $\mu\text{g}/\text{m}^3$)."

Hydrogen sulfide is toxic at much higher doses. According to OEHHA (2000), “[m]ost information on H₂S toxicity comes from studies that used levels of H₂S orders of magnitude above the standard of 0.03 ppm.”²⁶

The EPA advises that short term exposures to hydrogen sulfide be limited to less than 0.51 ppm in their Acute Emergency Guideline Limit (AEGL). The AEGL is “the airborne concentration (expressed as ppm or mg/m³) of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure.” The AEGL is approximately 100 times the incremental level that would be expected in residential areas near the Project.

The acute HI from shipping was less than 0.01 at the MEI, located in Point Molate. There was no acute HI from trucking, as DPM does not have an acute REL associated with it.

1.7.4 PM_{2.5} Concentrations

The incremental excess PM_{2.5} concentration for the mitigated Project case is 0.05 µg/m³ at the MEI, which is a worker receptor at a quarry surrounded by the Facility. The main driver of the PM_{2.5} concentration is emissions from the fluid catalytic cracker, but there are also reductions from removed sources that reduce the total PM_{2.5} concentration at that location. The maximally exposed residential receptor has a PM_{2.5} concentration far less than this value. This is well below the BAAQMD CEQA threshold of 0.3 µg/m³ for PM_{2.5} concentration.

As is shown in Table A4.3-HRA-17 the majority of the increase in PM_{2.5} concentration comes from Refinery Operations sources, specifically the fluid catalytic cracker and new hydrogen plant

1.8 CO CONCENTRATIONS FROM MODERNIZATION PROJECT OPERATION

Both the BAAQMD and the EPA have ambient air standards for CO concentration (BAAQMD, 2013; EPA, 2012c). The BAAQMD standards are more stringent than the EPA’s, with a 1-hour limit of 20 ppm and an 8-hour limit of 9 ppm. To compare the impacts of the Modernization Project to these standards, maximum hourly CO emissions were modelled.

²⁶ H₂S = hydrogen sulfide.

Maximum hourly emissions were assumed to be equal to annual average emissions multiplied by a factor of 2.4, consistent with the BAAQMD Engineering Evaluation for maximum hourly TAC emissions. Absolute Project emissions were used, as opposed to the “delta” between Project and Baseline, to determine the concentration from the entire Facility and not just the increase as a result of the Project. The maximum hourly emissions were modeled the same way as TAC emissions for the HRA. Concentrations in $\mu\text{g}/\text{m}^3$ were converted to ppm by the following equation:

$$C_{\text{ppm}} = C_{\mu\text{g}/\text{m}^3} \times \frac{24.45}{28.01} \times \frac{1}{1000}$$

Where:

24.45 = molar volume of an ideal gas at 25°C and 1 atm (L/mol)

28.01 = molar mass of CO (g/mol)

1000 = Unit conversion factor

The combined maximum 1-hour CO concentration from refinery and shipping sources is 2.6 ppm, well below the 20-ppm 1-hour standard. While 8-hour emissions were not estimated, the 1-hour concentration is a conservative estimate of 8-hour concentrations, and it is still less than the 9-ppm standard.
